Abstract. The footwear industry has strips of leather as one of its by-products. These leather residues, due to their high chromium content, can be regarded as a threat to the environment, particularly if no care is taken with their disposal. With the incorporation of the residues in ceramic products, after trituration, is possible to neutralise the eventual toxicity of chromium. In a laboratory study we produced prismatic bricks using clay from the region and incorporating 1, 3 and 5% (by mass) of leather residues. This corresponds at about 20, 60 and 100% (by apparent volume). The moulds were filled up with paste and, in order to have some compactness, the ceramic paste was compressed with a spatula. After that, it began the process of drying and burning the bricks. They were tested to flexure, compression and leaching. The results showed that the toxicity of chromium disappeared in the bricks. The mechanical tests showed a decrease in strength for the specimens with leather residue. The compressive strength decreases about 22% for 1% of incorporation of leather residue. However, as bricks were lighter and more porous, we can expect that they are better for thermal isolation.

Introduction

The valorisation of by-products of all the industries is recommended to minimise their disposal and treatment. In the case of leather residues, their possible toxicity increases the problems. The introduction of these residues in the raw material of ceramic products was experimented during this study. To have a homogeneous mixture, a mechanical mixer was used. After that small bricks were made by filling up steel moulds. In order to have some compactness a spatula was used to applied pressure in the material. Industrially, we have other methods, like extrusion, which can give better results [1].

The drying and burning processes of the factory were simulated in the laboratory. Drying [2,3] and burning [4] are very important phases for the production of ceramics. If dry and burn are not made correctly and slowly, the products can appear with cracks [5]. When the small bricks were completely burned the tests were started. Firstly, the bricks were tested to determine if they exhibit the characteristic of “Extraction Procedure Toxicity” [6]. Secondly, the possibility of bricks utilisation as construction material, in all the traditional applications [7], was analysed.

Bricks Production

For the bricks production was used clay from the region. The incorporations were 1, 3 and 5% of leather residues by mass of clay. Some control specimens, without any incorporation, were made. In order to have the same plasticity, the quantity of water was different for each incorporation (Table 1). The mixture was made in a mechanical mixer, till had a homogeneous paste. After, steel moulds were filled up with a help of a spatula. To obtain better compactness some pressure was made with a spatula.
The bricks had a prismatic form with the dimensions of 4x4x16 cm³. Four bricks for each incorporation were made. The bricks were removed from the moulds and the drying was made in five stages, in a drying stove, during 48 hours, with a temperature program from 30 to 100 °C. The burn was made in a muffle where the highest temperature (1000 °C) was reached approximately in 12 hours and the bricks were maintained at this temperature for 1 hour. After burning, specially in the bricks with 3 and 5% of residues incorporation, some exterior pores were observed. They are a result of residues carbonisation.

Leaching Tests

Leaching tests were performed in accordance with [8]. The material was ground so that it passed through a 9.5 mm sieve and then subjected to the extraction procedure. The samples obtained after filtration were analysed to determine total chromium (Cr_total) and hexavalent chromium (Cr(VI)). No significant concentrations were found (Table 2).

</tbody>
</table>

(*) Not detected.

Since low concentrations were obtained in these samples, no tests were made with the 1% of incorporation bricks. These results show that chromium compounds are, basically, immobilised in the clay matrix. On the other hand, facing these results, the possibility of chromium losses during the burn came up. So, determinations of Total Chromium (Cr_total) in the brick material and in the leather residues were made (Tables 3 and 4).

<td>21,80</td>
</tr>
</tbody>
</table>

Despite of the variation between the two analyses in the chromium concentrations of the control bricks (0% of incorporation) and leather residues, these results allow the rejection of the possibility
of chromium volatilisation during the burn. The chromium concentration in the brick material was never inferior to the expected value regarding the concentrations in the raw materials.

**Mechanical Testing**

Flexure and compressive tests were made in accordance with [10]. The flexure test was a three point one. The compressive tests were made in the two halves of the original prism after failure by flexure. As the surfaces were plane and without any depressions no capping had to be done.

The results are presented in Figures 1 and 2. With 1% of incorporation a decrease of 30% in the modulus of rupture and 22% in the compressive strength was found. The decrease of compressive strength is more significant for 3 and 5% of incorporation, around 45%. For the modulus of rupture, after the minimum with 1% of incorporation, the values increase with the quantity of leather residues, show the variation of the modulus of rupture and of the compressive strength with the percentage of incorporation.

![Graph showing Modulus of Rupture vs % of Incorporation](image)

**Fig. 1 - Variation of Modulus of Rupture with the % of Leather Residues Incorporation.**

The observation of the interior of the specimens after the compressive tests shows that the quantity of pores (black areas), increase with the incorporation of residues. The black areas resulted from the carbonisation of residues.

**Conclusion**

The incorporation of leather residues in the raw material used to produce bricks is possible. Losses of chromium (Cr(III) + Cr(VI)) on leaching or volatilisation during the burn were not verified. However, there is some decrease in mechanical properties (modulus of rupture and compressive strength). So, it is necessary to limit the incorporation to around 1% by mass of clay. As the residues are very light, this represents a reasonable volume.

The incorporation decreases the volumetric mass of the bricks. This is due to the increase of porosity because the residues carbonise during the burn and most part of the place occupied by them
results in holes. There is no problem on this because the alveolar bricks are good for thermal insulation and sound absorption [11]. So, with the incorporation of the leather residues there is some loss on mechanical strength but there is a winning in thermal and sound properties of the bricks. It is reasonable to think that these bricks can be used in partition walls.
