Synopsis

OBJECTIVE: Hair follicles are widely recognized as the preferential target and site of accumulation for nanoparticles after topical application. This feature is of particular importance for hair cosmetics, having the potential to refine the treatment of several hair follicle-related disorders. The aim of this work was to improve the preparation of Poly (D,L-lactide) (PLA) nanoparticles for *in vivo* follicular target and drug delivery.

METHODS: Envisaging a future industrial scale-up of the process, nanoprecipitation method was used to prepare PLA nanoparticles: the effect of several processing parameters on their properties was examined and the yield of nanoparticles formation determined. Encapsulation efficiencies and *in vitro* release profiles of lipophilic and hydrophilic model compounds were also assessed. *In vitro* cytotoxicity and *ex vivo* penetration studies were performed on a reference skin cell line (NCTC2455, human skin keratinocytes) and porcine skin, respectively.

RESULTS: Using acetone : ethanol (50 : 50, v/v) as the solvent phase, 0.6% (w/w) of Pluronic® F68 as a surfactant agent and agitation to mix the solvent and non-solvent phases, a monodispersed population of non-cytotoxic spherical nanoparticles of approximately 150 nm was obtained. The yield of nanoparticles for this formulation was roughly 90%. After encapsulation of model compounds, no significant changes were found in the properties of particles and the entrapment efficiencies were above 80%. The release kinetics of dyes from PLA nanoparticles indicate an anomalous transport mechanism (diffusion and polymer degradation) for Nile Red (lipophilic) and a Fickian diffusion of first order for fluorescein 5(6)-isothiocyanate (hydrophilic). *Ex vivo* skin penetration studies confirmed the presence of nanoparticles along the entire follicular ducts.

CONCLUSIONS: The optimized method allows the preparation of ideal PLA nanoparticles-based formulations for hair follicle targeting. PLA nanoparticles can effectively transport and release lipophilic and hydrophilic compounds into the hair follicles, and the yields obtained are acceptable for industrial purposes.

Résumé

OBJECTIF: Les follicules pileux sont largement reconnus comme la cible préférentielle et le site de l'accumulation des nanoparticules

après application topique. Cette caractéristique est particulièrement importante pour les produits cosmétiques pour les cheveux, ayant la possibilité d'affiner le traitement de plusieurs troubles des follicules de cheveux. Le but de ce travail était d'améliorer la préparation de nanoparticules poly (D,L-lactide) (PLA) pour une administration folliculaire *in vivo* ciblée de drogues.

MÉTHODES: En envisageant un avenir à l'échelle industrielle du procédé, une méthode de nanoprecipitation a été utilisée pour préparer des nanoparticules de PLA: l'effet de plusieurs paramètres de traitement sur leurs propriétés a été examiné et le rendement de la formation des nanoparticules a été déterminé. Les efficacités d'encapsulation et de profils de libération *in vitro* de composés modèles lipophiles et hydrophiles ont également été évaluées. La cytotoxicité *in vitro* et *ex vivo* des études de pénétration a été effectuée sur une lignée de cellules de peau de référence (NCTC2455, des kératinocytes de peau humaine) et la peau de porc, respectivement.

RÉSULTATS: En utilisant l'acétone : éthanol (50 : 50, v/v) comme phase solvant, 0,6% (p/p) de Pluronic® F68 à titre d'agent tensioactif et l'agitation pour mélanger les phases de solvant et de non-solvant, une population monodispersée des nanoparticules sphériques non cytotoxiques d'environ 150 nm a été obtenue. Le rendement de nanoparticules pour cette formulation était d'environ 90%. Après encapsulation de composés modèles, aucune modification significative n'a été observée dans les propriétés des particules et les efficacités de piégeage ont été supérieures à 80%. La cinétique de libération de colorants de nanoparticules de PLA indique un mécanisme de transport anormal (diffusion et dégradation de polymère) pour le rouge Nil (lipophile) et une diffusion selon Fick de premier ordre pour FITC (hydrophile). Les études de pénétration *ex vivo* de la peau ont confirmé la présence de nanoparticules sur tous les conduits folliculaires.

CONCLUSIONS: La méthode optimisée permet la préparation de formulations à base de nanoparticules de PLA, idéales pour ciblage du follicule pileux. Les nanoparticules de PLA peuvent effectivement transporter et libérer des composés lipophiles et hydrophiles dans les follicules pileux; les rendements obtenus sont acceptables à des fins industrielles.

Introduction

Nanoparticles are seen today as a key tool for the development of new cosmetics products: they improve the stability of various active ingredients, enhance their penetration into the skin and make some products more aesthetically pleasing [1].

Hair follicles are the preferential entrance point of nanoparticles into the skin [2]. The penetration within the follicular duct is dependent on their diameter, with smaller nanoparticles showing increased penetration depths [3]. Concomitantly, if nanoparticles are larger than 100 nm, they are not able to translocate into the viable epidermis, being trapped inside these structures [4]. This localized accumulation is especially important for the treatment of hair follicle-associated diseases (e.g. acne) and has the potential to revolutionize the treatment of human hair disorders (e.g. hirsutism, greying and alopecia) that have dramatic effects on the appearance, sociocultural status and self-esteem of the affected individuals [4–6]. As the drugs entrapped inside nanoparticles will be released just at the specific site of action, their bioavailability is enhanced. Consequently, minimal concentrations of active substances can be administered to achieve a desired effect, enabling the utilization of many pharmacological compounds for follicular therapy that otherwise would be unfeasible [3, 7, 8].

Polymeric nanoparticles are the most promising technology for follicular target as they exhibit great stability and efficiently mask the intrinsic properties of encapsulated drugs. These features facilitate the entrance of therapeutic agents that have low solubility on the sebum found inside the hair follicles [9]. Currently, nanoprecipitation (first introduced by Fessi *et al.*) is the most commonly used technique to formulate polymeric nanoparticles intended for topical application. In this method, the polymer is dissolved in an organic phase and the solution obtained is added to an aqueous phase (wherewith it is miscible). As the organic solvent flows away and diffuses in the aqueous phase, polymer molecules aggregate (due to the loss of solubility) and precipitate in the form of nanoparticles. Once the organic solvent is removed, the particles harden. Although it suffers the drawback of poor encapsulation efficiency of water-soluble drugs, nanoprecipitation allows the preparation of small nanoparticles with narrow size distribution in a simple, fast, economic and highly reproducible manner [9, 10].

In a recent study, Rancan *et al.* [4] proved the ability of Poly (D, L-lactide) nanoparticles (228 and 365 nm) prepared with the original nanoprecipitation method to efficiently target the hair follicles, reaching a maximal depth corresponding to the entry of sebaceous gland. In this work, we aimed to optimize this protocol in order to obtain smaller PLA nanoparticles. These nanoparticles will be able to achieve a deeper penetration into the hair follicles, allowing the delivery of drugs at the level of the hair bulb. The bulb of hair follicles is one of the most interesting targets for hair cosmetics due to the presence of hair matrix cells (that play an important role in the control of hair growth) and melanocytes (involved in the production of melanin and consequent coloration of hair shafts) [3, 6, 11].

The physical properties (and especially size) of nanoparticles obtained with nanoprecipitation are known to be dependent on many processing parameters: polymer, solvent, nature of the polymer–solvent interactions and non-solvent system [12]. Thus, the influence of the composition of the solvent phase, concentration of surfactant and technique used to mix both phase was studied. Once established the optimal conditions for the preparation of PLA nanoparticles, the entrapment efficiencies and release profiles of hydrophilic and lipophilic model compounds were determined. *Ex vivo* assays on porcine skin were performed to confirm the distribution of nanoparticles on the skin. Although the utilization of PLA is related to the fact that it is biocompatible, biodegradable and

already approved by Food and Drug Administration (FDA) for clinic use, the cytotoxicity of nanoparticles on a reference skin line was determined [13].

Materials and methods

Chemicals and solvents

Poly (D,L-lactide) (Mw = 18–24 kDa), Pluronic® F68 (suitable for cell culture), 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyl tetrazolium bromide (MTT), methanol (ACS reagent grade, ≥99.8%), Nile red (suitable for fluorescence), fluorescein 5(6)-isothiocyanate (suitable for fluorescence) and isopropyl myristate (Kosher grade, ≥98%) were purchased from Sigma-Aldrich (Sigma Chemical Co., St. Louis, MO, U.S.A.). Acetone, ethanol and dimethyl sulphoxide (DMSO) were of the highest grade commercially available and purchase from several suppliers.

Preparation of PLA nanoparticles

PLA nanoparticles were prepared based on the nanoprecipitation method [10]. Briefly, the polymer was dissolved in acetone – 2% (w/w) – and added to an aqueous phase containing Pluronic® F68 (solvent phase to aqueous phase ratio was 1 : 2). The concentration of surfactant in the resultant solution was 0.6% (w/w). After formation of nanoparticles, the organic phase was completely removed with a rotary evaporator. The aqueous suspensions of nanoparticle were stored at 4°C.

The cumulative effect of various processing parameters on the properties of PLA nanoparticles was studied. Three different techniques (agitation, sonication and homogenization) were used to mix the solvent and aqueous phases. *Agitation*: the organic phase was added dropwise into the aqueous phase under magnetic stirring at 100 r.p.m. The solution obtained was stirred overnight at the same velocity. *Sonication*: organic phase was added to the aqueous phase and the preparation submitted to an ultrasound treatment (power delivery controlled as percentage amplitude at 40%, 18 min, $5 \pm 1^\circ\text{C}$) [14]. The experimental set-up used was composed of an ultrasound probe (20 kHz Vibracell™ CV 33) fitted with a 3-mm diameter titanium micro-tip (Sonics and Materials Inc., Newtown, CT, U.S.A.). *Homogenization*: after addition of the solvent phase to the aqueous phase, the solution was homogenized for 18 min (constant flux of 40 mL min^{-1}), using an EmulsiFlex-C3 (Avestin, Ottawa, ON, Canada). PLA nanoparticles were also prepared using a fraction of a non-solvent (ethanol or water) in the solvent phase. Using titration, 55% and 10% (v/v) were determined as the maximum proportions of ethanol and water for the complete dissolution of the polymer. Finally, the effect of the concentration of Pluronic® F68 was studied.

Experimental yield of nanoparticles

The suspensions of nanoparticles were filtered to remove polymeric aggregates above the range of nano sizes. All the materials that contained the formulations were washed with acetone to dissolve the attached polymer. Methanol was added to precipitate PLA, and the solvents were removed on rotary evaporator. The polymer recovered in the filter and from the materials was dried and weighed (mass of aggregates, m_{agg}). The yield of nanoparticles was calculated as weight percent in relation to the initial amount of polymer used in formulation (m_{total}) [12]:

$$\text{Yield of Nanoparticles (\%)} = \frac{m_{\text{total}} - m_{\text{agg}}}{m_{\text{total}}} \times 100. \quad (1)$$

Particle size, size distribution and zeta-potential

The mean size and polydispersity (index from 0.0 to 1.0) of nanoparticles were assessed by Photon Correlation Spectroscopy (PCS), whereas laser Doppler anemometry (LDA) was employed for zeta (ζ)-potential. All measurements were performed at $25 \pm 1^\circ\text{C}$, using a ZetaSizer Nano ZS equipment (Malvern Instruments Ltd, Worcestershire, U.K.). The physical stability of suspensions was evaluated over 6 months, by weekly measurements of size, polydispersity index (PDI) and ζ -potential of PLA nanoparticles stored at 4°C .

Shape and surface morphology

The shape and surface morphology of nanoparticles were analysed by scanning transmission electron microscopy (STEM). The solutions containing nanoparticles were diluted and placed onto copper grids with carbon film 3-mm 400 meshes. Then, the observations were performed at 15 kV, using a NOVA Nano SEM 200 (FEI™, Hillsboro, OR, U.S.A.).

Entrapment and loading efficiencies

Dye-loaded nanoparticles were obtained employing the optimized nanoprecipitation protocol, with 1% (w/v) of Nile red (NR) or fluorescein 5(6)-isothiocyanate (FITC) being dissolved along with the polymer in the organic phase. NR and FITC were used as models of lipophilic and hydrophilic compounds, respectively. The aqueous suspensions of nanoparticles were dialysed against distilled water (Mw cut-off of 12.4 kDa) to remove free dye in the formulation. The suspensions were freeze-dried, nanoparticles powder obtained weighed and dissolved in acetone. The encapsulated drug was measured by Ultraviolet (UV)-Spectrophotometry. For Nile Red, measurements were performed with an excitation wavelength of 536 nm and emission wavelength of 608 nm. For FITC, 495 and 525 nm were used as excitation and emission wavelengths, respectively. The entrapment and loading efficiencies were calculated according to the following equations:

$$\text{Entrapment Efficiency (\%)} = \frac{m_{\text{encapsulated dye}}}{m_{\text{dye used in formulation}}} \times 100, \quad (2)$$

$$\text{Loading Efficiency (\%)} = \frac{m_{\text{encapsulated dye}}}{m_{\text{nanoparticles}}} \times 100. \quad (3)$$

In vitro release profiling

Aqueous suspensions of dye-loaded nanoparticles were added to vials containing the same volume of isopropyl myristate (IPM). The chemical structure of IPM resembles that of sebum components, and consequently, it can simulate the skin surface/interior of the hair follicle ducts [4]. The systems were constantly stirred at 37°C . To assess the release profile of NR, at fixed time points (0, 2, 4, 6, 8, 12 and 24 h), a small aliquot of the lipophilic phase was collected and replaced with the same volume of IPM; fluorescence intensity was measured at 570 nm (excitation: 520 nm) [15]. For FITC-loaded nanoparticles, at the same time points, the hydrophilic phase was collected, centrifuged to deposit nanoparticles and

supernatant fluorescence measured at 525 nm (excitation at 495 nm). The supernatant was discharged, nanoparticles were dispersed in water and added again to the lipophilic phase [16]. The amount of released dyes was determined using a calibration curve, obtained from the values of fluorescence intensity of standard samples. The percentages were calculated with respect to the initial amount present in the nanoparticles.

With the release rates of fluorochromes, it was possible to achieve the release behaviour of the dyes from the PLA nanoparticles. Thus, the release data were fitting to the empirical relationship given by Ritger–Peppas equation (Eq. 4). The n value on the equation is the diffusion exponent characteristic of the release mechanism, and it is given by the relation between the fraction drug release at time t (M_t/M_∞). t is the release time and k is the kinetic constant.

$$\frac{M_t}{M_\infty} = k \times t^n \quad (4)$$

To determine the value of n , Eq. 4 is transformed and n is the slope value of the plot of $\log$ (% release) versus $\log t$ (Eq. 5).

$$\log(\% \text{ released}) = \log\left(\frac{M_t}{M_\infty}\right) = \log k + n \times \log t. \quad (5)$$

Ex vivo skin penetration assay

Abdominal porcine skin was excised from freshly slaughtered pigs at Central Carnes – Matadouro Central de Entre Douro e Minho, Lda. (Lousado, Portugal), following approved protocol by DGV-Direção Geral de Veterinária. Subcutaneous fat was removed, the skin was washed with phosphate-buffered saline (PBS, pH 7.4) and placed in Franz Diffusion Cells (PermeGear Inc., Bethlehem, PA, U.S.A.) with the *stratum corneum* facing the donor compartment and the dermis facing the receptor compartment. After the acclimatization of the tissue to the receptor phase (PBS, pH 7.4, thermostatically maintained at 37°C), the skin surface was incubated with dye-loaded nanoparticles suspensions for 24 h. Vertical histological cuts (20 μm thickness) of frozen skin sections were made using a Leica CM1900 cryostat (Leica Microsystems, Nussloch, Germany). The distribution of nanoparticle inside the skin was investigated in histological cuts by bright field and fluorescence microscopy – Leica DM 5000B Microscope (Leica Microsystems) [4].

In vitro cytotoxicity

NCTC2544 (human skin keratinocytes) cells were cultured in 75-cm² culture flasks containing Dulbecco's modified Eagle's medium (DMEM) supplemented with 7% (v/v) foetal bovine serum (FBS) and 1% (v/v) of penicillin/streptomycin solution. At every 2–3 days, cell culture medium was refreshed.

To assess the skin toxicity of PLA nanoparticles, NCTC2544 cells were seeded on 24-well tissue culture polystyrene plates (TPP, Switzerland) at the initial density of 4.5×10^4 cells per well. The next day, fresh medium containing different volume fractions of aqueous suspensions of PLA nanoparticles was added to the cells. Before each experiment, the suspensions were sterilized with 0.45- μm filter (SARSTEDT, Nümbrecht, Germany). Several controls were performed simultaneously: the death control with 10% (v/v) DMSO, the 100% viability control with just fresh medium and the solvent dilution controls with water instead of PLA nanoparticle suspensions at 5%, 10% and 20% (v/v). Cell viability at 24, 48 and 72 h

of exposure were determined using the MTT assay – a quantitative colorimetric assay where the yellow tetrazolium salt MTT is reduced by living cells to blue formazan crystals [17]. Absorbance values at 570 and 690 nm were measured in a Spectramax 340PC microplate reader (Molecular Devices, Sunnyvale, CA, U.S.A.). Percentages of cell viability were calculated considering the 100% cell viability control.

Statistical analysis

All the results are expressed as mean value $\pm$ standard deviation (SD) of at least three experiments. Statistical analysis was performed with GRAPHPAD PRISM version 6.05 for Windows (GraphPad Software, La Jolla, CA, U.S.A.), using analysis of variance (ANOVA). The differences were considered statistically significant at $P < 0.05$.

Results and discussion

Preparation of PLA nanoparticles suitable for hair follicle targeting

The developed nanoparticles had a net negative surface charge. It is known that PLA chains have carboxyl groups at their extremity and, when they aggregate to form nanoparticles, these groups tends to be located in the aqueous environment, creating a negative surface charge [18]. Independently of the tested processing conditions, the value of ζ -potential was around -20 mV (data not shown).

Effect of the preparation technique

The size and size distribution of nanoparticles prepared with agitation, sonication and homogenization are shown in Fig. 1. The particles prepared with sonication were substantially smaller and more homogeneous than those produced by homogenization. This is due to the greater amount of energy supplied to the system during the sonochemical treatment. It is known that higher amounts of

energy results in higher shear stress, which is inversely related to size and size distribution of particles obtained [19]. Although the size of nanoparticles obtained with sonication and agitation did not display significant differences, the use of an agitation-based protocol provided the lowest values of PDI. The dropwise addition used in this technique can induce a better spread of the organic phase into the aqueous phase, leading to precipitation of small and highly homogenous polymer aggregates in the form of nanoparticles [20]. Thus, agitation was the selected procedure for the following experiments.

Effect of the addition of a non-solvent to the solvent phase

The addition of a portion of a non-solvent to the solvent phase can be advantageous for the preparation of a smaller nanoparticles by nanoprecipitation [10]. In Fig. 2, the properties of nanoparticles prepared with acetone : water (90 : 10, v/v) and acetone : ethanol (45 : 55, v/v) are compared to those obtained when only acetone was used as the solvent phase. Contrarily to expected, the use of water induced a slight increase in the mean size of nanoparticles. As PLA has low affinity to water, the polymer chains become more shrunken and overlapped, avoiding its efficient dispersion in the solvent phase. Consequently, the precipitation of larger polymer clusters can occur, and particles with larger sizes are obtained [21, 22]. The same effect can explain the increase in PDI of nanoparticles prepared with both binary mixtures tested in this study. Nevertheless, the populations obtained are still considered monodispersed. On the other hand, acetone : ethanol (45 : 55, v/v) promoted a decrease in the mean diameter of PLA nanoparticles. This can be explained by the high affinity of the mixture to water (acetone : ethanol is the more polar solvent phase tested). According to the literature, the higher the affinity of the solvent phase to the non-solvent phase, the faster its diffusion and particles with smaller sizes are formed [23–25]. Considering the balance between the size and size distribution of nanoparticles obtained, acetone : ethanol was chosen as the optimal solvent phase for the preparation of PLA nanoparticles.

Figure 1 Size and size distribution of poly (D,L-lactide) (PLA) nanoparticles prepared by nanoprecipitation, using three different techniques to mix the solvent phase (acetone) with the aqueous phase; concentration of Pluronic® F68 in the resultant solution was 0.6% (w/w). Data were analysed by one-way ANOVA, followed by *post-hoc* Dunnett's test. $**P \leq 0.01$; $***P \leq 0.001$ or $****P \leq 0.0001$, compared to Agitation (used as reference as it provided the smallest mean size and size distribution of PLA nanoparticles).

Figure 2 Size and size distribution of poly (D,L-lactide) nanoparticles prepared by nanoprecipitation, using 10% (v/v) of water or 55% (v/v) of ethanol in the solvent phase (acetone). Agitation was used to mix the solvent phase with the aqueous phase; concentration of Pluronic® F68 in the resultant solution was 0.6% (w/w). Data were analysed by one-way ANOVA, followed by *post-hoc* Dunnett's test. $*P \leq 0.05$; $**P \leq 0.01$; $***P \leq 0.001$, compared to the results obtained when only Acetone was used as the solvent phase.

Effect of the surfactant concentration

Increasing concentrations of polymeric surfactants are responsible for an enhancement of the aqueous phase viscosity which can decrease the wavy movement, collision, aggregation (especially during the early stages of the precipitation) and further size of the particles [26]. Nevertheless, in this work, as the concentration of Pluronic® F68 increased, the mean diameter of PLA nanoparticles prepared also increased in a statistically significant manner (Fig. 3). It is possible that the increased viscosity of the aqueous phase had hindered the diffusion of the solvent phase. As mentioned before, larger nanoparticles are formed for slower solvent phase diffusion rates [23–25]. Also, it is known that Pluronic® F68 is adsorbed on the surface on nanoparticles and due to the hydration of Poly (ethylene glycol; PEG) present in its composition, the size of nanoparticles can increase. The hydrodynamic radii of PEG polymers highly hydrated (two to three water molecules per ethylene glycol unit) is approximately 5- to 10-fold greater than would be predicted by their nominal molecular weight [27]. Regarding the PDI, until 1.5% (w/w) of surfactant, a stabilizer effect was observed. On the other hand, at 2% (w/w), the effect of the viscosity overpowers the stabilizer effect of the surfactant, justifying the high heterogeneity of the particle populations [15, 25, 28–30]. Taking both results into consideration, 0.6% (v/v) of Pluronic® F68 enables the preparation of the most adequate PLA nanoparticles for follicular targeting.

Efficiency of nanoparticles formation

The calculated nanoparticles yield, using 55% of ethanol in the solvent phase, was $87 \pm 7\%$. At high percentages of ethanol, the diffusion of the organic phase into the aqueous phase is very fast and higher amounts of polymer can immediately precipitate before its agglomeration into particles occurs [23–25]. Thus, lower fractions of this solvent in the organic phase were tested to clarify its effects on the yield of PLA nanoparticles. Contrarily to what was expected, no significant increase on the yield of nanoparticles was observed (Table I). However, for volume fractions of ethanol below 55%, the

Figure 3 Size and size distribution of poly (D,L-lactide) nanoparticles prepared by nanoprecipitation, using increasing concentrations of surfactant (Pluronic® F68). Agitation was used to mix the solvent phase – acetone : ethanol (45 : 55, v/v) – with the aqueous phase. Data were analysed by one-way ANOVA, followed by *post-hoc* Dunnett's test. ** $P \leq 0.01$; *** $P \leq 0.001$ or **** $P \leq 0.0001$, compared to 0.6% (concentration used in the previous optimizations).

Table I Effect of decreasing volume fractions of ethanol (used in the solvent phase) on the yield and properties of poly (D,L-lactide) nanoparticles

Volume fraction of ethanol (%)	Yield of nanoparticles (%)	Z-Average (nm)	PDI	Zeta-potential (mV)
55	87 ± 7	146 ± 2	0.078 ± 0.007	-21.5 ± 1.3
50	91 ± 1	$151 \pm 1^*$	0.074 ± 0.011	$-18.1 \pm 0.5^*$
45	93 ± 2	$138 \pm 1^{**}$	0.074 ± 0.010	$-15.3 \pm 0.9^{**}$

These particles were prepared by nanoprecipitation, using agitation to mix the solvent phase and the aqueous phase; concentration of Pluronic® F68 in the resultant solution was 0.6% (w/w). Data were analysed by one-way ANOVA, followed by *post-hoc* Dunnett's test. * $P \leq 0.05$ and ** $P \leq 0.01$, compared to the maximal tested volume fraction of ethanol (55%).

method seems to be more reproducible as lower standard deviations were obtained.

The properties of nanoparticles, prepared with different volume fractions of ethanol in the solvent phase, were also compared (Table I). Despite the PDI remained unchanged, alterations on the size and ζ -potential were registered. For 45% (v/v), there was a considerable decrease on the mean diameter and ζ -potential (absolute value) of nanoparticles when compared to the values obtained at other ethanol percentages. The value of surface charge obtained can be problematic during the storage of nanoparticles because it will not be negative enough to prevent their aggregation by electrostatic repulsions [31]. Regarding to 50% (v/v) of ethanol, a slight increase in the mean size and surface charge of nanoparticles was noticed, but the use of these particles for hair follicle targeting is not impaired. Consequently, 50% (v/v) was chosen as the optimal volume fraction of ethanol in the solvent phase: it constitutes the best compromise between yield of nanoparticles, reproducibility of the method and suitability of nanoparticles properties when follicular targeting is intended.

Morphology and physical stability of nanoparticles

The morphology of PLA nanoparticles obtained with the optimal conditions stated before can be observed in Fig. 4(A). The shape of these particles is spherical. This morphology is optimal for a drug delivery system, as it provides the longest diffusion pathways and protection of incorporated drugs due to the minimum contact with the aqueous environment [26]. Moreover, this suspension proved to be physically stable after 6 months of storage at 4°C as no significant variations in size, PDI and ζ -potential (data not shown) were noticed (Fig. 4B).

Entrapment efficiency of model compounds

The dye-loaded PLA nanoparticles did not show significant differences on mean diameter, PDI and ζ -potential when compared to the empty nanoparticles. Also, no significant changes were noticed between dye-loaded nanoparticles formulations and empty nanoparticles formulations, regarding the efficiency of nanoparticles formation (data not shown).

The encapsulation of both dyes proved to be highly efficient, and the results obtained are shown in Table II. Although a high entrapment efficiency was expected for NR (a lipophilic compound),

Figure 4 STEM photograph ($\times 25\,000$ magnification) (A) and stability over 6 months (B) of poly (D,L-lactide) nanoparticles. These particles were prepared by nanoprecipitation, using agitation to mix the solvent phase – acetone : ethanol (50 : 50, v/v) – and the aqueous phase; concentration of Pluronic® F68 in the resultant solution was 0.6% (w/w). Data were analysed by one-way ANOVA, followed by *post-hoc* Dunnett's test. No statistical significant differences were found, compared to time point 0 months.

Table II Effect of the compounds nature (lipophilic or hydrophilic) on the entrapment and loading efficiencies into poly (D,L-lactide) nanoparticles

Entrapped compound	Entrapment efficiency (%)	Loading efficiency (%)
Nile red	89 $\pm$ 7	0.0488 $\pm$ 0.0019
FITC	83 $\pm$ 2	0.0508 $\pm$ 0.0004

These particles were prepared by nanoprecipitation, dissolving 1% (w/v) of Nile Red or fluorescein 5(6)-isothiocyanate (FITC) in the solvent phase – acetone : ethanol (50 : 50, v/v). Agitation was used to mix solvent phase with the aqueous phase, and the concentration of Pluronic® F68 in the resultant solution was 0.6% (w/w).

the results obtained for FITC are surprising taking into account that usually, nanoprecipitation is ineffective to encapsulate compounds of hydrophilic nature. Due to their water-soluble nature, they rapid partitioning from the core of nanoparticles into the aqueous phase, leading to considerable decrease in their encapsulation efficiency [22]. However, the composition of the solvent phase used

Figure 5 *In vitro* release profile of Nile red and fluorescein 5(6)-isothiocyanate (FITC) from poly (D,L-lactide) nanoparticles. These particles were prepared by nanoprecipitation, using agitation to mix the solvent phase – acetone : ethanol (50 : 50, v/v) – with the aqueous phase; the concentration of Pluronic® F68 in the resultant solution was 0.6% (w/w). The initial concentration of dyes in the solvent phase was 1% (w/v).

makes its diffusion rate and consequently solidification of the nanoparticles very fast. Consequently, that leakage of large amounts of FITC is avoided. The increased viscosity of the organic phase also helps to increase the diffusional resistance of FITC, and it was previously involved on the achievement of high encapsulation efficiency of some other molecules [19].

In addition to the entrapment efficiency, the loading efficiency was also determined for both dyes (Table II). As formulations have similar yields of nanoparticles and entrapment efficiencies, it is not surprising that no significant differences were found for loading efficiencies obtained for NR-loaded and FITC-loaded nanoparticles.

Release profile of dyes from PLA nanoparticles

In vitro release of NR and FITC was evaluated using artificial sebum (IPM) (Fig. 5). Both kinetic profiles exhibit a typical biphasic release phenomenon. The initial burst release is attributed to the fraction of the dyes which is adsorbed/weakly bound to the large surface area of nanoparticles or entrapped in the matrix near the surface of particles. The following slow and constant release over the remaining time is due to the diffusion of compounds and erosion of the polymeric matrix [32].

When particles were placed in contact with IPM (0 h), higher amounts of FITC were immediately released from nanoparticles. As mentioned before, during the formation of nanoparticles, FITC have a tendency to rapidly partitioning into the aqueous phase (due to its hydrophilic nature). Despite this phenomenon usually lead to low entrapment efficiencies, in this study, that did not happen. However, it is possible that high amounts of FITC have been poorly entrapped in the matrix near to the nanoparticles surface. Upon contact with IPM, these FITC molecules are immediately released due to the destabilization of nanoparticles [31, 33].

After the first time point, NR showed a faster release from PLA nanoparticles: 100% was completely achieved within 24 h. This is tightly coupled to its lipophilic nature. Upon contact with

IPM, a destabilization of the particles occurs (due to the dissolution of the polymer in the lipophilic phase), allowing the solvent to penetrate into their cores. As lipophilic compounds have high affinity to IPM, their partitioning between the core of nanoparticles and the lipophilic solvent occurs easily, leading to their rapid diffusion out of the particles [34]. This rapid leakage contributes to destabilize even more the particles, leading to a loss of their particulate state, which promotes a further increase in the release of the entrapped lipophilic compound [35]. The

Table III Dye release kinetic data obtained from fitting experimental release of Nile Red and fluorescein 5(6)-isothiocyanate (FITC) from poly (D,L-lactide) nanoparticles to Ritger–Peppas modified equation, where n is the diffusion exponent and R^2 is the correlation coefficient

Released compound	n	R^2
Nile red	0.847	0.993
FITC	0.209	0.959

fast *in vitro* release of NR is of great interest in the particular case of hair follicle targeting because it is possible to assume that *in vivo*, the full release of lipophilic drugs in the hair follicle canal will occur before the excretion of nanoparticles due to sebum production (8 days) [36]. On the other hand, as hydrophilic compounds (like FITC) have poor solubility in the lipophilic solvent, they partitioning into IPM at a slower rate and their diffusion outside the particles is hindered, resulting in prolonged release kinetics [35, 37].

To confirm the mechanism of drug release stated above for NR (diffusion and polymeric matrix degradation) and FITC (mainly diffusion), the empirical expression proposed by Ritger–Peppas (based on the Fickian diffusion equation) was used. For a sphere, a diffusion of first order is observed when has the limiting value of 0.43. Between 0.43 and 0.85, anomalous transport is observed coupling Fickian diffusion and polymer degradation. Finally, for $n = 0.85$, Case II transport (polymer relaxation/degradation) occurs, leading to a zero-order release [26]. For PLA nanoparticles produced in this work, the n value obtained for the tested dyes are shown in Table III. According to the values, anomalous transport (diffusion and polymer degradation) and Fickian diffusion of first order govern the release of Nile Red

Figure 6 Bright field (top) and fluorescence (bottom) images of hair follicles (A,C) and *stratum corneum* (B,D) of porcine skin cryosections, after 24 h of incubation with Nile red-loaded (A,B) and fluorescein 5(6)-isothiocyanate-loaded (C,D) poly (D,L-lactide) nanoparticles ($\times 5$ magnification). These particles were prepared by nanoprecipitation, using agitation to mix the solvent phase – acetone : ethanol (50 : 50, v/v) – with the aqueous phase; the concentration of Pluronic® F68 in the resultant solution was 0.6% (w/w). The initial concentration of dyes in the solvent phase was 1% (w/v).

Figure 7 NCTC2544 cell viability (MTT assay) was determined at 24, 48 and 72 h of exposure to different volume fractions of poly (D,L-lactide) nanoparticles suspension. These particles were prepared by nanoprecipitation, using agitation to mix the solvent phase – acetone : ethanol (50 : 50, v/v) – and the aqueous phase; concentration of Pluronic® F68 in the resultant solution was 0.6% (w/w). Values for tested samples are presented in relation to the cells control (cells cultured with medium scored for 100% of viability). Data were analysed by two-way ANOVA, followed by *post-hoc* Tukey's test. * $P \leq 0.05$; ** $P \leq 0.01$; *** $P \leq 0.001$ or **** $P \leq 0.0001$, when conditions were compared with the corresponding medium dilution control or among each other.

(lipophilic) and FITC (hydrophilic) from PLA nanoparticles, respectively.

Penetration of nanoparticles into the hair follicles after topical application

The penetration profile of PLA nanoparticles was assessed on porcine skin which resembles human skin regarding its permeability properties [38]. NR-loaded and FITC-loaded nanoparticles were observed inside the hair follicles along the entire follicular duct (Fig. 6A,C), reaching the hair bulb (where melanocytes can be found) [3]. Although some nanoparticles have been trapped in the *stratum corneum*, they did not reach the viable epidermis as no fluorescence was detected in this skin layer (Fig. 6B,D). These findings confirm that the obtained PLA nanoparticles efficiently and selectively target the hair follicles after topical application, even without the use of massage. Massage is used in *ex vivo* studies to simulate the hair movement that occurs physiologically under *in vivo* conditions and facilitate the entrance of nanoparticles into the hair follicles [39].

Cytotoxicity of nanoparticles using a reference skin cell line

The cytotoxicity of PLA nanoparticles was assessed in *in vitro* cultured keratinocytes, as a measure of the skin toxicity. NCTC2544 cells were exposed to different concentrations of nanoparticles ranging from 165 to 660 $\mu\text{g mL}^{-1}$ [5–20% (v/v) of the optimal formulation], and cell viability measured at 24, 48 and 72 h. According to the results (Fig. 7), none of the tested amounts of PLA nanoparticles had a biological significant toxicity (cell viability >78%). For an exposure period of 24 h, there was no decrease in keratinocytes viability when compared to the medium dilution control. For longer

periods of exposure, besides the medium dilution effect (statistically significant just for a 72-h exposure to 20% (v/v) of formulation), a decrease in viability was observed for concentrations higher than 165 $\mu\text{g mL}^{-1}$ (10–20%), with varied degrees of statistical significance. Despite this, the range of nanoparticles concentrations tested can be safely applied to the skin.

Conclusions

On this study, an optimized nanoprecipitation method is described. PLA nanoparticles prepared are well suited to penetrate into the hair follicles duct, reaching the hair bulb without reaching the viable epidermis. This site-specific target of hair follicles has great impact in hair follicle therapies. The high yield obtained, the stability over 6 months, the absence of toxicity in a skin cell line model, the efficient entrapment and suitable *in vitro* release of lipophilic and hydrophilic model compounds make these formulations viable for industrial purposes when the development of new cosmetics for human hair is intended.
