\section{Introduction}

Weighted automata were introduced in Schützenberger’s classical paper [38]. They are of great importance in computer science [10], arising in different areas of application, such as speech recognition [27], image compression [2], control theory [20] and quantitative modelling [25,3]. They can be seen as a generalisation of non-deterministic automata, where each transition has a weight associated to it. This weight is an element of a semiring, representing, for example, the cost or probability of taking the transition.

The behaviour of weighted automata is usually given in terms of weighted languages (also called formal power series [37, 6]), that are functions assigning a weight to each finite string \( w \in A^* \) over an input alphabet \( A \). For computing the weight given to a certain word, the semiring structure plays a key role: the multiplication of the semiring is used to accumulate the weight of a path by multiplying the weights of each transition in the path, while the addition of the semiring computes the weight of a string \( w \) by summing up the weights of the paths labelled with \( w \) [24]. Alternatively, the behaviour of weighted automata can be expressed in terms of weighted bisimilarity [8], that is, an extension of bisimilarity (for non-deterministic
automata) subsuming several kinds of quantitative equivalences such as, for example, probabilistic bisimilarity [21]. As in the case of non-deterministic automata, (weighted) bisimilarity implies strictly (weighted) language equivalence.

In this paper, we study linear weighted automata, which are “deterministic” weighted automata where the set of states forms a vector space. A linear weighted automaton can be viewed as the result of “determinizing” an ordinary weighted automaton with weights in a generic field, using some kind of “weighted powerset construction”. As such, linear weighted automata are typically infinite state. The key point is that the linear structure of the state space allows for finite representations of these automata and effective algorithms operating on them.

To be more specific, the goal of the present paper is to undertake a systematic study of the behavioural equivalences and minimisation algorithms for (linear) weighted automata. To achieve this goal, we will benefit from a coalgebraic perspective on linear weighted automata. The theory of coalgebras offers a unifying mathematical framework for the study of many different types of state-based systems and infinite data structures. Given a functor \( G : C \rightarrow C \) on a category \( C \), a \( G \)-coalgebra is a pair consisting of an object \( X \) in \( C \) (representing the state space of the system) and a morphism \( f : X \rightarrow GX \) (determining the dynamics of the system). Under mild conditions, functors \( G \) have a final coalgebra (unique up to isomorphism) into which every \( G \)-coalgebra can be mapped via a unique so-called \( G \)-homomorphism. The final coalgebra can be viewed as the universe of all possible \( G \)-behaviours: the unique homomorphism into the final coalgebra maps every state of a coalgebra to a canonical representative of its behaviour. This provides a general notion of behavioural equivalence (\( \approx_G \)): two states are equivalent if and only if they are mapped to the same element of the final coalgebra.

Our first contribution in this paper is to recast both weighted bisimilarity and weighted language equivalence in the theory of coalgebras. We see weighted automata for a field \( \mathbb{K} \) and alphabet \( A \), as coalgebras of the functor \( V \mathcal{W} = \mathbb{K} \times \mathbb{K}^{-A} \) on \( \text{Set} \) (the category of sets and functions). Concretely, a \( W \)-coalgebra consists of a set of states \( X \) and a function \( (o, t) : X \rightarrow \mathbb{K} \times \mathbb{K}^{X^A} \) where, for each state \( x \in X \), \( o : X \rightarrow \mathbb{K} \) assigns an output weight in \( \mathbb{K} \) and \( t : X \rightarrow \mathbb{K}^{X^A} \) assigns a function in \( \mathbb{K}^{X^A} \).

For each symbol \( a \in A \) and state \( x \in X \), \( t(x)(a)(x') \) is a weight \( k \in \mathbb{K} \) representing the weight of a transition from \( x \) to \( x' \) with label \( a \), in symbols \( x \xrightarrow{a^k} x' \). If \( t(x)(a)(x') = 0 \), then there is no \( a \)-labelled transition from \( x \) to \( x' \). Note that there could exist several weighted transitions with the same label outgoing from the same state: \( x \xrightarrow{a_k} x_1, x \xrightarrow{a_k} x_2, \ldots, x \xrightarrow{a_k} x_n \).

Adapting the above reasoning, we model linear weighted automata as coalgebras of the functor \( \mathcal{L} = \mathbb{K} \times (-)^A \) on \( \text{Vect} \) (the category of vector spaces and linear maps). A linear weighted automaton consists of a vector space \( V \) and a linear map \((o, t) : V \rightarrow \mathbb{K} \times V^A \) where, as before, \( o : V \rightarrow \mathbb{K} \) defines the output and \( t : V \rightarrow V^A \) the transition structure. More precisely, for each vector \( v \in V \) and \( a \in A \), \( (v)(a)(v') \) means that there is a transition from \( v \) to \( v' \) with label \( a \), in symbols \( v \xrightarrow{a} v' \). Note that the transition structure is now “deterministic”, since for each vector \( v \) and input \( a \in A \) there is only one vector \( v' \in V \). When \( V = \mathbb{K}^X \), each vector \( v \in V \) can be seen as a linear combination of states \( x_1, \ldots, x_n \in X \), i.e., \( v = k_1x_1 + \cdots + k_nx_n \) for some \( k_1, \ldots, k_n \in \mathbb{K} \). Therefore, the transitions \( x \xrightarrow{a_k} x_1, \ldots, x \xrightarrow{a_k} x_n \) of a weighted automaton correspond to a single transition \( x \xrightarrow{(k_1x_1 + \cdots + k_nx_n)} \).

We show that \( \approx_{V \mathcal{W}} \) (i.e., the behavioural equivalence induced by \( V \mathcal{W} \)) coincides with weighted bisimulation while \( \approx_{\mathcal{L}} \) coincides with weighted language equivalence. Determinisation is the construction for moving from ordinary weighted automata and weighted bisimilarity to linear weighted automata and weighted language equivalence. Similar to the powerset construction, determinisation combines all the states within one vector, but unlike the determinisation of a non-deterministic automaton, the resulting state space will not be finite but forming a vector space of finite dimension. On this respect, our determinisation differs from the construction described by Mohri [27] for a subclass of weighted automata with weights on a semiring (rather than a field), which associates states of the determinised weighted automaton with a set of states of the original weighted automaton.

Once we have fixed the mathematical framework, we investigate three different types of algorithms for computing \( \approx_{\mathcal{L}} \). These algorithms work under the assumption that the underlying vector space has finite dimension. The first is a forward algorithm that generalises the usual partition-refinement algorithm for ordinary automata: one starts by decreeing as equivalent states with the same output values, then refines the obtained relation by separating states for which outgoing transitions go to states that are not already equivalent. Linearity of the automata plays a crucial role to ensure termination of the algorithm. Indeed, the equivalences computed at each iteration can be represented as finite-dimensional subspaces in the given vector space. The resulting descending chain of subspaces must therefore converge in a finite number of steps, despite the fact that the state space itself is infinite. We also show that each iteration of the algorithm coincides with the equivalence generated by each step of the (standard) construction of the final coalgebra via the final sequence. The minimal linear representation of weighted automata over a field was first considered by Schützenberger [38]. This algorithm was reformulated in a more algebraic and slightly simplified fashion in the book of Berstel and Reutenauer [6]. Their algorithm is different from our method, as it is related to the construction of a basis for a subgroup of a free group. Further, no evident connections can be traced between their treatment and the notions of bisimulation and coalgebras.

The second algorithm proceeds in a similar way, but uses a backward procedure. It has been introduced by the third author together with linear weighted automata [7]. In this case, the algorithm starts from the complement – in a precise geometrical sense – of the relation identifying vectors with equal weights. Then it incrementally computes the space of all states that are backward reachable from this relation. The largest bisimulation is obtained by taking the complement of this space. The advantage of this algorithm over the previous one is that the size of the intermediate relations is typically much smaller. The presentation of this algorithm in [7] is somewhat more concrete, as there is no attempt at a coalgebraic
treatment and the underlying field is fixed to \( \mathbb{R} \) (for example, this leads to using orthogonal complements rather than dual spaces and annihilators, which we consider in Section 4). No connection is made with rational series.

Finally, the third algorithm is new and uses the fact that equivalent states are mapped by the unique homomorphism into the same element of the final coalgebra. We characterise the final morphism in terms of so-called rational weighted languages (which are also known as rational formal power series). This characterisation is useful for the computation of the kernel of the final homomorphism, which consists of weighted language equivalence. Taking again advantage of the linear structure of our automata, calculating the kernel of the above homomorphism will correspond to solving a linear system of equations.

The results in this paper are presented for weighted automata with weights taken from a field, as opposed to the more general and classical definition where weights from a semiring are considered. This restriction is convenient for presentation purposes and, as we will discuss in Section 6, many of the results (but not all) can be extended to semirings.

A coalgebraic perspective on weighted automata is by no means the only approach to understand their structure and properties, as is already clear from the various references to related work mentioned above (more will follow in Section 6). We have found the application of coalgebra as a general framework for the study of dynamical systems and infinite behaviour in the present setting useful for a number of reasons, which we shall briefly discuss next.

An important feature of the coalgebraic methodology is that once a class of systems is identified as the class of coalgebras of a certain type (formally, a functor), then several things come for free, following from the general theory of universal coalgebra [32]: (i) the semantics or behaviour of each system is obtained by a unique homomorphism into the final coalgebra; (ii) with each coalgebra type, a canonical notion of behavioural equivalence is associated; (iii) the homomorphism into the final coalgebra identifies all and only those states that are equivalent; (iv) consequently, the image of the system under this final coalgebra homomorphism is its minimisation with respect to the canonical notion of behavioural equivalence. Yet another advantage of the general perspective of coalgebra is that it offers a framework in which it is possible to relate different types of systems in a rigorous manner.

By identifying, in the present setting, the different types of weighted automata (notably, classical branching weighted automata and linear weighted automata) as different types of coalgebras, we obtain immediately an appropriate notion of behavioural equivalence for each of them. As a consequence, we have been able to put the different existing notions of equivalence of weighted automata (weighted bisimilarity and weighted language equivalence) into a coherent perspective. Using their coalgebraic characterisations, it was relatively straightforward to give a precise description of the transformation of (branching) weighted automata into linear weighted automata, by means of a generalised version of the well-known powerset construction. Our coalgebraic characterisation has furthermore led to a canonical description of the minimisation of linear weighted automata, in Section 5. The details of this construction are very similar to the use of rational power series and linear systems of equations [6]. What is pleasant about the coalgebraic approach is that the present description of the minimisation of linear weighted automata is an instance of the canonical and general insights from universal coalgebra, mentioned above.

Structure of the paper. In Section 2 we introduce weighted automata and coalgebras. We also show that \( \mathcal{W} \)-coalgebras characterise weighted automata and weighted bisimilarity. In Section 3.2, after recalling some preliminary notions of linear algebras, we show that each weighted automaton can be seen as a linear weighted automaton, i.e., an \( \mathcal{L} \)-coalgebra. This change of perspective allows us to coalgebraically capture weight language equivalence.

In Section 4, we show the forward and the backward algorithm while, in Section 5, we first introduce a syntactic characterisation of rational weighted languages (which are also known as rational formal power series). This characterisation is useful for the computation of the kernel of the final homomorphism, which consists of weighted language equivalence. Taking again advantage of the linear structure of our automata, calculating the kernel of the above homomorphism will correspond to solving a linear system of equations.

In Section 2.3 and 4.3 show some interesting minor results that could be safely skipped by the not interested reader. The presentation is self-contained and does not require any prior knowledge on the theory of coalgebras.

2. Weighted automata as coalgebras

We will first introduce the fundamental definitions and facts about weighted automata, weighted bisimilarity and their characterisation as coalgebras over \( \text{Set}, \) the category of sets and functions. We will next introduce weighted language equivalence over weighted automata. In the final subsection, we will discuss a further equivalence that naturally arises from the theory of coalgebras; this equivalence will play no role in the rest of the paper, though.

2.1. Fundamental definitions

First we fix some notation. We will denote sets by capital letters \( X, Y, Z, \ldots \) and functions by lower case \( f, g, h, \ldots \). Given a set \( X \), id\(_{X}\) is the identity function and, given two functions \( f : X \to Y \) and \( g : Y \to Z \), \( g \circ f \) is their composition. The product of two sets \( X, Y \) is \( X \times Y \) with the projection functions \( \pi_{1} : X \times Y \to X \) and \( \pi_{2} : X \times Y \to Y \). The product of two functions \( f_{1} : X_{1} \to Y_{1} \) and \( f_{2} : X_{2} \to Y_{2} \) is \( f_{1} \times f_{2} \) defined for all \( (x_{1}, x_{2}) \in X_{1} \times X_{2} \) by \( (f_{1} \times f_{2})(x_{1}, x_{2}) = (f_{1}(x_{1}), f_{2}(x_{2})) \).

The disjoint union of \( X, Y \) is \( X + Y \) with injections \( \iota_{1} : X \to X + Y \) and \( \iota_{2} : Y \to X + Y \). The union of \( f_{1} : X_{1} \to Y_{1} \) and \( f_{2} : X_{2} \to Y_{2} \) is \( f_{1} + f_{2} \) defined for all \( z \in X + Y \) by \( f_{1} + f_{2}((\iota_{1}(x), \iota_{2}(y))) = \iota_{1}(x) \) (for \( i \in \{1, 2\} \)). The set of functions \( \varphi : X \to Y \) is denoted by \( \text{X}^{Y} \). For \( f : X_{1} \to X_{2} \), the function \( f^{Y} : X_{1}^{Y} \to X_{2}^{Y} \) is defined for all \( \varphi \in X_{1}^{Y} \) by \( f^{Y}(\varphi) = \lambda y \in Y. f(\varphi(y)) \).
collection of finite subsets of $X$ is denoted by $P_\omega(X)$ and the empty set by $\emptyset$. For a set of letters $A$, $A^*$ denotes the set of all finite words over $A$; $\epsilon$ the empty word; and $w_1w_2$ the concatenation of words $w_1, w_2 \in A^*$.

We fix a field $\mathbb{K}$. We use $k_1, k_2, \ldots$ to range over elements of $\mathbb{K}$. The sum of $\mathbb{K}$ is denoted by $+$, the product by $\cdot$, the additive identity by $0$ and the multiplicative identity by $1$. The support of a function $\varphi$ from a set $X$ to a field $\mathbb{K}$ is the set $\{x \in X \mid \varphi(x) \neq 0\}$.

Weighted automata are a generalisation of ordinary automata where transitions in addition to an input letter have also a weight in a field $\mathbb{K}$ and each state is not just accepting or rejecting but has an associated output weight in $\mathbb{K}$.

Formally, a weighted automaton $(\mathbb{X}, (\varphi, \delta))$, where each $\varphi$ associates a weight to each transition. We shall use the notation $\varphi(a)$ from a set $X$ to a field $\mathbb{K}$ is the set $\{x \in X \mid \varphi(x) \neq 0\}$.

Weighted automata are a generalisation of ordinary automata where transitions in addition to an input letter have also a weight in a field $\mathbb{K}$ and each state is not just accepting or rejecting but has an associated output weight in $\mathbb{K}$.

Fig. 1. The weighted automata $(X, (\varphi_X, \delta_X))$ and $(Y, (\varphi_Y, \delta_Y))$ (from left to right). The dashed arrows denote the $\mathbb{K}$-homomorphism $h : X \to Y$. This induces the equivalence relation $R_h = X \times X$ that equates all the states in $X$.

For a concrete example, let $\mathbb{K} = \mathbb{R}$ (the field of real numbers) and $A = \{a, b\}$ and consider the weighted automata $(X, (\varphi_X, \delta_X))$ and $(Y, (\varphi_Y, \delta_Y))$ in Fig. 1. Their representation as matrix is the following:

$$O_X = \begin{pmatrix} 1 & 1 & 1 \end{pmatrix}, \quad T_{X_a} = \begin{pmatrix} 1 & 0 & 0 \\ 1 & 3 & 0 \\ 1 & 0 & 3 \end{pmatrix}, \quad T_{X_b} = \begin{pmatrix} 3 & 3 & 3 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \quad O_Y = (1), \quad T_{Y_a} = (3), \quad T_{Y_b} = (3).

Weighted bisimilarity generalises the abstract semantics of several kind of probabilistic and stochastic systems. This has been introduced by Buchholz in [8] for weighted automata with a finite state space. Here we extend that definition to (possibly infinite states) automata with finite branching, i.e., those $(X, (\varphi, \delta))$ such that for all $x \in X$, $\delta(a)(x) \neq 0$ for finitely many $x'$. This will be needed in the sequel, when we model weighted automata co algebraically, to ensure that the final co algebra exists (the final co algebra can be thought of the universe of possible behaviours and will be used to provide semantics to each state of the automaton).

Hereafter we will always implicitly refer to weighted automata with finite branching. Moreover, given an $x \in X$ and an equivalence relation $R \subseteq X \times X$ we will write $[x]_R$ to denote the equivalence class of $x$ with respect to $R$.

Definition 1. Let $(X, (\varphi, \delta))$ be a weighted automaton. An equivalence relation $R \subseteq X \times X$ is a weighted bisimulation if for all $(x_1, x_2) \in R$, it holds that:

1. $\varphi(x_1) = \varphi(x_2)$,
2. $\forall a \in A, x' \in X, \sum_{x'' \in [x']_R} \delta(x_1)(a)(x'') = \sum_{x'' \in [x']_R} \delta(x_2)(a)(x'')$.

Weighted bisimilarity (in symbols $\sim_w$) is defined as the largest weighted bisimulation.

For instance, the relation $R_h$ in Fig. 1 is a weighted bisimulation.

Now, we will show that weighted automata and weighted bisimilarity can be suitably characterised through coalgebras.

We first recall some basic definitions about coalgebras. Given a functor $\mathcal{G} : C \to C$ on a category $C$, a $\mathcal{G}$-coalgebra is an object $X$ in $C$ together with an arrow $f : X \to \mathcal{G}X$. For many categories and functors, such a pair $(X, f)$ represents a transition system, the type of which is determined by the functor $\mathcal{G}$. Vice versa, many types of transition systems (e.g., deterministic automata, labelled transition systems and probabilistic transition systems) can be captured by a functor.
A \( G \)-homomorphism from a \( G \)-coalgebra \((X, f)\) to a \( G \)-coalgebra \((Y, g)\) is an arrow \( h : X \to Y \) preserving the transition structure, i.e., such that the following diagram commutes.

\[
\begin{array}{ccc}
X & \xrightarrow{h} & Y \\
\downarrow{f} & & \downarrow{g} \\
GX & \xrightarrow{\varphi h} & GY
\end{array}
\]

A \( G \)-coalgebra \((\Omega, \omega)\) is said to be final if for any \( G \)-coalgebra \((X, f)\) there exists a unique \( G \)-homomorphism \( \llbracket \cdot \rrbracket^G_X : X \to \Omega \). Final coalgebra can be viewed as the universe of all possible \( G \)-behaviours: the unique homomorphism \( \llbracket \cdot \rrbracket^G_X : X \to \Omega \) maps every state of a coalgebra \( X \) to a canonical representative of its behaviour. This provides a general notion of behavioural equivalence: two states \( x_1, x_2 \in X \) are \( G \)-behaviourally equivalent \((x_1 \approx G x_2)\) iff \( \llbracket x_1 \rrbracket^G_X = \llbracket x_2 \rrbracket^G_X \).

The functors corresponding to many well-known types of systems are shown in \cite{32}. In this section we will show a functor \( \mathcal{W} : \text{Set} \to \text{Set} \) such that \( \approx_{\mathcal{W}} \) coincides with weighted bisimilarity. In order to do that, we need to introduce the field valuation functor.

**Definition 2 (Field valuation functor).** Let \( K \) be a field. The field valuation functor \( \mathbb{K}_{\omega} : \text{Set} \to \text{Set} \) is defined as follows. For each set \( X \), \( \mathbb{K}_{\omega}^X \) is the set of functions from \( X \) to \( K \) with finite support. For each function \( h : X \to Y \), \( \mathbb{K}_{\omega}^h : \mathbb{K}_{\omega}^X \to \mathbb{K}_{\omega}^Y \) is the function mapping each \( \varphi \in \mathbb{K}_{\omega}^X \) into \( \varphi^h \in \mathbb{K}_{\omega}^Y \) defined, for all \( y \in Y \), by

\[
\varphi^h(y) = \sum_{x \in h^{-1}(y)} \varphi(x).
\]

Note that the above definition employs only the additive monoid of \( K \), i.e., the element 0 and the + operator. For this reason, such functor is often defined in literature (e.g., in [16]) for commutative monoids instead of fields.

We need two further ingredients. Given a set \( B \), the functor \( B \times - : \text{Set} \to \text{Set} \) maps every set \( X \) into \( B \times X \) and every function \( f : X \to Y \) into \( id_B \times f : B \times X \to B \times Y \). Given a finite set \( A \), the functor \( -^A : \text{Set} \to \text{Set} \) maps \( X \) into \( X^A \) and \( f : X \to Y \) into \( f^A : X^A \to Y^A \) (recall that \( f^A \) is defined for all \( \varphi \in X^A \) as \( f^A(\varphi) = \lambda a \in A. f(\varphi(a)) \)).

Now, the corresponding functor to weighted automata with input alphabet \( A \) over the field \( K \) is \( \mathcal{W} = K \times (\mathbb{K}_{\omega})^A : \text{Set} \to \text{Set} \). Note that every function \( f : X \to \mathcal{W}(X) \) consists of a pair of functions \((o, t)\) with \( o : X \to K \) and \( t : X \to (\mathbb{K}_{\omega})^A \). Therefore any \( \mathcal{W} \)-coalgebra \((X, f)\) is a weighted automaton \((X, (o, t))\) (and vice versa).

**Proposition 1.** (See [39].) The functor \( \mathcal{W} \) has a final coalgebra.

**Proof.** By [17, Theorem 7.2], the fact that \( \mathcal{W} \) is bounded is enough to guarantee the existence of a final coalgebra. Intuitively, a functor \( F \) is bounded by some cardinal number \( c \), if for all \( F \)-coalgebras \((X, f)\) and all states \( x \in X \), the set of states “reachable” from \( x \) has cardinality smaller than or equal to \( c \). For instance the powerset functor \( P(-) \) is not bounded (and does not have final coalgebra [32]), while the finite powerset functor \( P_{\omega}(-) \) is bounded by \( \omega \). Also, the functor \( \mathcal{W} \) is bounded by \( \omega \) because of the finite branching condition. \( \square \)

In order to show that the equivalence induced by the final \( \mathcal{W} \)-coalgebra \((\approx_{\mathcal{W}})\) coincides with weighted bisimilarity \((\approx_w)\), it is instructive to spell out the notion of \( \mathcal{W} \)-homomorphism. A function \( h : X \to Y \) is a \( \mathcal{W} \)-homomorphism between weighted automata \((X, (o_X, t_X))\) and \((Y, (o_Y, t_Y))\) if the following diagram commutes:

\[
\begin{array}{ccc}
X & \xrightarrow{h} & Y \\
\downarrow{(o_X, t_X)} & & \downarrow{(o_Y, t_Y)} \\
\mathbb{K} \times (\mathbb{K}_{\omega}^X)^A & \xrightarrow{id \times (\mathbb{K}_{\omega}^h)^A} & \mathbb{K} \times (\mathbb{K}_{\omega}^Y)^A
\end{array}
\]

This means that for all \( x \in X, y \in Y, a \in A \),

\[
o_X(x) = o_Y(h(x)) \quad \text{and} \quad \sum_{x' \in h^{-1}(y)} t_X(x)(a)(x') = t_Y(h(x))(a)(y).
\]

For every \( \mathcal{W} \)-homomorphism \( h : (X, (o_X, t_X)) \to (Y, (o_Y, t_Y)) \), the equivalence relation \( R_h = \{(x_1, x_2) \mid h(x_1) = h(x_2)\} \) is a weighted bisimulation. Indeed, by the properties of \( \mathcal{W} \)-homomorphisms and by definition of \( R_h \), for all \( (x_1, x_2) \in R_h \)

\[
o_X(x_1) = o_Y(h(x_1)) = o_Y(h(x_2)) = o_X(x_2)
\]

Here we are implicitly assuming that \( C \) is a concrete category [1], i.e., there exists a forgetful functor \( U : C \to \text{Set} \). By writing \( x_1, x_2 \in UX \) and by \( [x_1]^X_1 \), we mean \( U(\llbracket \cdot \rrbracket^G_X)_{x_1} \).
and for all $a \in A$, for all $y \in Y$

$$\sum_{x' \in e^{-1}(y)} t_x(x_1)(a)(x') = t_Y(h(x_1))(a)(y) = t_Y(h(x_2))(a)(y) = \sum_{x' \in e^{-1}(y)} t_x(x_2)(a)(x').$$

Trivially, the latter implies that for all $x' \in X$

$$\sum_{x' \in [x']_R} t_x(x_1)(a)(x') = \sum_{x' \in [x']_R} t_x(x_2)(a)(x').$$

For an example look at the function $h$ depicted by the dashed arrows in Fig. 1: $h$ is a $\mathcal{V}$-homomorphism and $R_h$ is a weighted bisimulation.

Conversely, every bisimulation $R$ on $(X, \langle o_X, t_X \rangle)$ induces a coalgebra $(X/R, \langle o_{X/R}, t_{X/R} \rangle)$ where $X/R$ is the set of all equivalence classes of $X$ w.r.t. $R$ and $o_{X/R} : X/R \to \mathbb{K}$ and $t_{X/R} : X/R \to (\mathcal{X}_A^\mathcal{V})^{X/R}$ are defined for all $x_1, x_2 \in X$, $a \in A$ by

$$o_{X/R}(\lfloor x_1 \rfloor_R) = o_X(x_1), \quad t_{X/R}(\lfloor x_1 \rfloor_R)(\lfloor x_2 \rfloor_R) = \sum_{x' \in [x_2]_R} t_X(x_1)(a)(x').$$

Note that both $o_{X/R}$ and $t_{X/R}$ are well-defined (i.e., independent from the choice of the representative) since $R$ is a weighted bisimulation. Most importantly, the function $\varepsilon_R : X \to X/R$ mapping $x$ into $[x]_R$ is a $\mathcal{V}$-homomorphism.

![Diagram](image_url)

**Theorem 1.** Let $(X, \langle o, t \rangle)$ be a weighted automaton and let $x_1, x_2$ be two states in $X$. Then, $x_1 \sim_W x_2$ iff $x_1 \approx_{\mathcal{V}} x_2$, i.e., $x_1^\mathcal{V} = x_2^\mathcal{V}$.

**Proof.** The proof follows almost trivially from the above observations.

If $x_1 \approx_{\mathcal{V}} x_2$, i.e., $[x_1]^\mathcal{V} = [x_2]^\mathcal{V}$, then $(x_1, x_2) \in R_{[-1]^\mathcal{V}}$ and $R_{[-1]^\mathcal{V}}$ is a weighted bisimulation because $[\cdot]^\mathcal{V}$ is a $\mathcal{V}$-homomorphism. Thus $x_1 \sim_W x_2$.

If $x_1 \sim_W x_2$, then there exists a weighted bisimulation $R$ such that $(x_1, x_2) \in R$. Let $(X/R, \langle o_{X/R}, t_{X/R} \rangle)$ and $\varepsilon_R : X \to X/R$ be the $\mathcal{V}$-coalgebra and the $\mathcal{V}$-homomorphism described above. Since there exists a unique $\mathcal{V}$-homomorphism from $(X, \langle o_X, t_X \rangle)$ to the final coalgebra, then $[\cdot]^\mathcal{V} = [\cdot]_{X/R} \circ \varepsilon_R$. Since $\varepsilon_R(x_1) = \varepsilon_R(x_2)$, then $[x_1]^\mathcal{V} = [x_2]^\mathcal{V}$, i.e., $x_1 \approx_{\mathcal{V}} x_2$. □

### 2.2. Weighted language equivalence

The semantics of weighted automata can also be defined in terms of weighted languages. A weighted language over $A$ and $\mathbb{K}$ is a function $\sigma : A^* \to \mathbb{K}$ assigning to each word in $A^*$ a weight in $\mathbb{K}$. For each word $w$ in $(X, \langle o, t \rangle)$, the function $l_X : X \to \mathbb{K}^{A^*}$ assigns to each state $x \in X$ its recognised weighted language. For all words $a_1 \ldots a_n \in A^*$, it is defined by

$$l_X(x)(a_1 \ldots a_n) = \sum \{ k_1 \cdots k_n \mid x = x_1 \xlongmapsto{a_1k_1} \cdots x_n \text{ and } o(x_n) = k \}.$$

We will often use the following characterisation: for all $w \in A^*$,

$$l_X(x)(w) = \begin{cases} o(x), & \text{if } w = \varepsilon; \\ \sum_{x' \in X} (l_X(x)(a')) \cdot l_X(x')(w'), & \text{if } w = a w'. \end{cases}$$

Two states $x_1, x_2 \in X$ are said to be weighted language equivalent (denoted by $x_1 \sim_w x_2$) if $l_X(x_1) = l_X(x_2)$. In [8], it is shown that if two states are weighted bisimilar then they are also weighted language equivalent. For completeness, we recall here the proof.

**Proposition 2.** $\sim_w \subseteq \sim_l$.

**Proof.** We prove that if $R$ is a weighted bisimulation, then for all $(x_1, x_2) \in R$, $l_X(x_1) = l_X(x_2)$. We use induction on words $w \in A^*$. 
If \( w = \epsilon \), then \( I_X(x_1)(w) = o(x_1) \) and \( I_X(x_2)(w) = o(x_2) \) since \( R \) is a weighted bisimulation.

If \( w = aw' \), then

\[
I_X(x_1)(w) = \sum_{x' \in X} (t(x_1)(a)(x') \cdot I_X(x')(w')).
\]

By induction hypothesis for all \( x'' \in [x']_R \), \( I_X(x'')(w') = I_X(x')(w') \). Thus in the above summation we can group all the states \( x'' \in [x']_R \) as follows:

\[
I_X(x_1)(w) = \sum_{[x'] \in X/R} \left( \sum_{x'' \in [x']_R} t(x_1)(a)(x'') \cdot I_X(x')(w') \right).
\]

Since \( (x_1, x_2) \in R \) and \( R \) is a weighted bisimulation, the above summation is equal to

\[
\sum_{[x] \in X/R} \left( \sum_{x'' \in [x']_R} t(x_2)(a)(x'') \cdot I_X(x')(w') \right)
\]

that, by the previous arguments, is equal to \( I_X(x_2)(w) \).

The inverse inclusion does not hold: the states \( x_1, y_1, z_1 \) and \( u_1 \) in Fig. 2 are language equivalent but they are not equivalent according to weighted bisimilarity.

2.3. On the difference between \( \mathcal{W} \)-bisimilarity and \( \mathcal{W} \)-behavioural equivalence

We conclude this section with an example showing the difference between \( \mathcal{W} \)-behavioural equivalence (and hence weighted bisimulation) and another canonical equivalence notion from the theory of coalgebra, namely \( \mathcal{W} \)-bisimilarity. This result is not needed for understanding the next sections, and therefore this subsection can be safely skipped.

The theory of coalgebras provides an alternative definition of equivalence, namely \( \mathcal{G} \)-bisimilarity (\( \simeq_\mathcal{G} \)), that coincides with \( \mathcal{G} \)-behavioural equivalence whenever the functor \( \mathcal{G} \) preserves weak pullbacks [32]. In the case of weighted automata, the functor \( \mathcal{W} \) does not preserve weak pullbacks and \( \simeq_\mathcal{W} \) is strictly included into \( \simeq_\mathcal{W} \). Since weighted automata are one of the few interesting cases where this phenomenon arises, we now show an example of two states that are in \( \simeq_\mathcal{W} \), but not in \( \simeq_\mathcal{W} \) (the paper [15] was of great inspiration for the construction of this example).

First, let us instantiate the general coalgebraic definition of bisimulation and bisimilarity to the functor \( \mathcal{W} \). A \( \mathcal{W} \)-bisimulation between two \( \mathcal{W} \)-coalgebras \( (X, (o_X, t_X)) \) and \( (Y, (o_Y, t_Y)) \) is a relation \( R \subseteq X \times Y \) such that there exists \( (o_R, t_R): X \rightarrow \mathcal{W}(R) \) making the following diagram commute. The largest \( \mathcal{W} \)-bisimulation is called \( \mathcal{W} \)-bisimilarity (\( \simeq_\mathcal{W} \)).

\[
\begin{array}{ccc}
X & \xrightarrow{\pi_1} & R \\
\downarrow{(o_X, t_X)} & \quad & \downarrow{(o_R, t_R)} \\
\mathcal{W}(X) & \overset{\mathcal{W}(\pi_1)}{\longleftarrow} & \mathcal{W}(R) \\
\downarrow{\mathcal{W}(\pi_2)} & & \downarrow{\mathcal{W}(\pi_2)} \\
\mathcal{W}(Y) & \overset{\mathcal{W}(\pi_2)}{\longrightarrow} & \mathcal{W}(Y)
\end{array}
\]

Note that the actual definition of \( \simeq_\mathcal{W} \) relates the states of a single automaton. We can extend it in order to relate states of possibly distinct automata: given \( (X, (o_X, t_X)) \) and \( (Y, (o_Y, t_Y)) \), the states \( x \in X \) and \( y \in Y \) are equivalent w.r.t. \( \approx_\mathcal{W} \) iff \( [x]_R = [y]_R \).

Consider now the coalgebras in Fig. 3: \( x_1 \approx_\mathcal{W} y_1 \), but \( x_1 \not\approx_\mathcal{W} y_1 \). For the former, it is enough to observe that the functions \( h_1 \) and \( h_2 \) (represented by the dashed arrows) are \( \mathcal{W} \)-homomorphisms, and by uniqueness of \( [x]_R = [y]_R \). For \( x_1 \not\approx_\mathcal{W} y_1 \), note that there exists \( R \subseteq X \times Y \) that is a \( \mathcal{W} \)-bisimulation and such that \( (x_1, y_1) \in R \). Since \( x_2 \) and \( x_3 \) have different output values than \( y_1 \), then neither \( (x_2, y_1) \) nor \( (x_3, y_1) \) can belong to a bisimulation. Thus, the only remaining non-empty relation on \( X \times Y \) is the one equating just \( x_1 \) and \( y_1 \), i.e., \( R = \{(x_1, y_1)\} \). But this is not a \( \mathcal{W} \)-bisimulation since there exists no \( (o_R, t_R) \) making the leftmost square of the above diagram commute. In order to understand this fact, note that \( \pi_1^{-1}(x_2) = \emptyset \) and \( \pi_1^{-1}(x_3) = \emptyset \). Thus for all possible choices of

---

**Fig. 2.** The states \( x_1, y_1, z_1 \) and \( u_1 \) in the above automaton recognise the language mapping \( a0 \) into 2 and the other words into 0. Although they are all language equivalent, they are not bisimilar.

---

**Fig. 3.** The states \( x_1, y_1, z_1 \) and \( u_1 \) in the above automaton recognise the language mapping \( a0 \) into 2 and the other words into 0. Although they are all language equivalent, they are not bisimilar.
is a linearly independent set of vectors that spans the whole space if none of its elements can be expressed as the linear combination of the remaining ones. A linearly independent set spans the whole space (or maps). Given a set $X$, and a vector space $V$, the set $V^X$ (i.e., the set of functions $\varphi: X \to V$) carries a vector space structure where sum and scalar product are defined point-wise. Hereafter we will use $V^X$ to denote both the vector space and scalar product are defined in the obvious way. This is called the free vector space generated by $X$ and can be thought of as the space spanned by $X$ and can be thought of as the space spanned by $X$. A linearly independent set spans the whole space (or maps). Given a set $X$, and a vector space $V$, the set $V^X$ (i.e., the set of functions $\varphi: X \to V$) carries a vector space structure where sum and scalar product are defined point-wise. Hereafter we will use $V^X$ to denote both the vector space and scalar product are defined in the obvious way. This is called the free vector space generated by $X$ and can be thought of as the space spanned by $X$.

$\langle \sigma_R, t_R \rangle$, the function $VV(\pi_1) \circ \langle \sigma_R, t_R \rangle$ maps $(x_1, y_1)$ into a pair $(k, \varphi)$ where $\varphi(a)(x_2) = 0$ and $\varphi(a)(x_3) = 0$. On the other hand, the square, we have that $\langle \sigma_X, t_X \rangle \circ \pi_1(x_1, x_1) = \langle \sigma_X(x_1), t_X(x_1) \rangle$ and $t_X(x_1)(a)(x_2) = 1$ and $t_X(x_1)(a)(x_3) = -1$.

It is interesting to observe that transitions with weight play a special role for having $x_1 \approx_{VW} y_1$ and $x_1 \not\approx_{VW} y_1$. Similar examples can be constructed by using commutative monoids which are not zero-sum free (a monoid is said to be zero-sum free if $k_1 + k_2 = 0$ implies $k_1 = 0 = k_2$). We refer the interested reader to [16], where the relationship between zero-sum free monoids and weak-pullback preserving functors is discussed in detail.

### 3. Linear weighted automata as linear coalgebras

In this section, we will introduce linear weighted automata as coalgebras for an endofunctor $L : \text{Vect} \to \text{Vect}$, where $\text{Vect}$ is the category of vector spaces and linear maps over a field $\mathbb{K}$. The goal of this approach is to characterise weighted language equivalence as the behavioural equivalence induced by the final $L$-coalgebra.

#### 3.1. Preliminaries

First we fix some notations and recall some basic facts on vector spaces and linear maps. We use $v_1, v_2, \ldots$ to range over vectors and $V, W, \ldots$ to range over vector spaces on a field $\mathbb{K}$. Given a vector space $V$, a vector $v \in V$ and a $k \in \mathbb{K}$, the scalar product is denoted by $k \cdot v$ (or $kv$ for short). The space spanned by an $I$-indexed family of vectors $B = \{v_i\}_{i \in I}$ is the space spanned by all of $v$ such that

$$v = k_1 v_1 + k_2 v_2 + \cdots + k_n v_n$$

where for all $j$, $v_j \in B$. In this case, we say that $v$ is a linear combination of the vectors in $B$. A set of vectors is linearly independent if none of its elements can be expressed as the linear combination of the remaining ones. A basis for the vector $V$ is a linearly independent set of vectors that spans the whole $V$. All the bases of $V$ have the same cardinality which is called the dimension of $V$ (denoted by $\dim(V)$). If $(v_1, \ldots, v_n)$ is a basis for $V$, then each vector $v \in V$ is equal to $k_1 v_1 + \cdots + k_n v_n$ for uniquely determined $k_1, \ldots, k_n \in \mathbb{K}$. For this reason, each vector $v$ can be represented as an $n \times 1$-column vector

$$v = \begin{pmatrix} k_1 \\ \vdots \\ k_n \end{pmatrix}.$$  

We use $f, g, \ldots$ to range over linear maps. Identity and composition of maps are denoted as usual. If $B_V = (v_1, \ldots, v_n)$ and $B_W = (w_1, \ldots, w_m)$ are, respectively, the bases of the vector spaces $V$ and $W$, then every linear map $f : V \to W$ can be represented as an $m \times n$-matrix. Indeed, for each $v \in V$, $v = k_1 v_1 + \cdots + k_n v_n$ and $f(v) = k_1 f(v_1) + \cdots + k_n f(v_n)$, by linearity of $f$. For each $v_j$, $f(v_j)$ can be represented as an $m \times 1$-column vector by taking as basis $B_W$. Thus the matrix corresponding to $f$ (w.r.t. $B_V$ and $B_W$) is the one having as $i$-th column the vector corresponding to $f(v_i)$. In this paper we will use capital letters $F, G, \ldots$ to denote the matrices corresponding to linear maps $f, g, \ldots$ in lower case. By multiplying the matrix $F$ with vector $v$ (in symbols, $F \times v$) we can compute $f(v)$. More generally, matrix multiplication corresponds to composition of linear maps, in symbols:

$$g \circ f = G \times F.$$  

The product of two vector spaces $V, W$ is written as $V \times W$, and the product of two linear maps $f_1, f_2$ is $f_1 \times f_2$, defined as for functions. It will be clear from the context whether $\times$ refer to the multiplication of matrices or to the product of spaces (or maps). Given a set $X$, and a vector space $V$, the set $V^X$ (i.e., the set of functions $\varphi : X \to V$) carries a vector space structure where sum and scalar product are defined point-wise. Hereafter we will use $V^X$ to denote both the vector space and the underlying carrier set. Given a linear map $f : V_1 \to V_2$, the linear map $f^X : V^X_1 \to V^X_2$ is defined as for functions. If $A$ is a finite set we can conveniently think $V^A$ as the product of $V$ with itself for $|A|$-times ($|A|$ is the cardinality of $A$). A linear map $f : U \to V^A$ can be decomposed in a family of maps indexed by $A$, $f = \{f_a : U \to V\}_{a \in A}$, such that for all $u \in U$, $f_a(u) = f(u)(a)$.

For a set $X$, the set $\mathbb{K}^X$ (i.e., the set of all finite support functions $\varphi : X \to \mathbb{K}$) carries a vector space structure where sum and scalar product are defined in the obvious way. This is called the free vector space generated by $X$ and can be thought
of as the space spanned by the elements of $X$: each vector $k_1x_1 + k_2x_2 + \cdots + k_nx_n$ corresponds to a function $\varphi : X \to \mathbb{R}$ such that $\varphi(x_i) = k_i$ and for all $x \notin \{x_j \mid j = 1, \ldots, n\}$, $\varphi(x) = 0$; conversely, each finite support function $\varphi$ corresponds to a vector $(\varphi(x_1), \varphi(x_2), \ldots, \varphi(x_n))$.

A fundamental property holds in the free vector space generated by $X$: for all functions $f$ from $X$ to the carrier-set of a vector space $V$, there exists a linear map $f^* : \mathbb{R}^X \to V$ that is called the linearisation of $f$. For all $\varphi \in \mathbb{R}^X$, $f = k_1x_1 + k_2x_2 + \cdots + k_nx_n$ and $f^*(\varphi) = k_1f(x_1) + k_2f(x_2) + \cdots + k_nf(x_n)$.

\begin{center}
\begin{tikzpicture}
\node (X) at (1,0) {$X$};
\node (V) at (3,0) {$V$};
\node (f) at (1.5,0) {$f^*$};
\node (eta) at (1.5,1) {$\eta_X$};
\draw[->] (X) edge [bend right] node[above] {$f^*$} (V);
\end{tikzpicture}
\end{center}

Note that $f^*$ is the only linear map such that $f = f^* \circ \eta_X$, where $\eta_X(x)$ is the function assigning 1 to $x$ and 0 to all the other elements of $X$.

The kernel $\ker(f)$ of a linear map $f : V \to W$ is the subspace of $V$ containing all the vectors $v \in V$ such that $f(v) = 0$. The image $\text{im}(f)$ of $f$ is the subspace of $W$ containing all the $w \in W$ such that $w = f(v)$ for some $v \in V$. If $V$ has finite dimension, the kernel and the image of $f$ are related by the following equation:

$$\dim(V) = \dim(\ker(f)) + \dim(\text{im}(f)).$$

(1)

Given two vector spaces $V_1$ and $V_2$, their intersection $V_1 \cap V_2$ is still a vector space, while their union $V_1 \cup V_2$ might not. Instead of union we consider the coproduct of vector spaces: we write $V_1 + V_2$ to denote the space span($V_1 \cup V_2$) (note that in the category of vector spaces, product and coproduct coincide).

### 3.2. From weighted automata to linear weighted automata

We have now all the ingredients to introduce linear weighted automata and a coalgebraic characterisation of weighted language equivalence.

**Definition 3 (lwa).** A linear weighted automaton (LWA, for short) with input alphabet $A$ over the field $\mathbb{K}$ is a coalgebra for the functor $\mathcal{L} = \mathbb{K} \times -: \text{Vect} \to \text{Vect}$.

More concretely [7], an LWA is a pair $(V, (o, t))$, where $V$ is a vector space (representing the state space), $o : V \to \mathbb{K}$ is a linear map associating to each state its output weight and $t : V \to V^A$ is a linear map that for each input $a \in A$ associates a next state (i.e., a vector) in $V$. We will write $v_1 \xrightarrow{a} v_2$ for $t(v_1)(a) = v_2$.

The behaviour of linear weighted automata is expressed in terms of weighted languages. The language recognised by a vector $v \in V$ of an LWA $(V, (o, t))$ is defined for all words $a_1 \ldots a_n \in A^*$ as $[v]^t_v(a_1 \ldots a_n) = o(v_n)$ where $v_n$ is the vector reached from $v$ through $a_1 \ldots a_n$, i.e., $v \xrightarrow{a_1} \ldots \xrightarrow{a_n} v_n$. We will often use the following (more compact) characterisation: for all $w \in A^*$,

$$[v]^t_v(w) = \begin{cases} o(v), & \text{if } w = \varepsilon; \\ t((v)(a))^t_v(w'), & \text{if } w = aw'. \end{cases}$$

Here we use the notation $[\cdot]^t_v$ because this is the unique $\mathcal{L}$-homomorphism into the final $\mathcal{L}$-coalgebra. In Section 3.3, we will provide a proof for this fact and we will also discuss the exact correspondence with the function $I_X$ introduced in Section 2.

A given weighted automaton $(X, (o, t))$, we can build a linear weighted automaton $(\mathbb{R}^X, (o^2, t^2))$, where $\mathbb{R}^X$ is the free vector space generated by $X$ and $o^2$ and $t^2$ are the linearisations of $o$ and $t$. If $X$ is finite, we can represent $t^2$ and $o^2$ by the same matrices that we have introduced in the previous section for $t$ and $o$. Fixing an ordering $x_1, \ldots, x_n$ of the states in $X$, we have a basis for $\mathbb{R}^X$, i.e., every vector $v \in \mathbb{R}^X$ is equal to $k_1x_1 + \cdots + k_nx_n$ and it can be represented as an $n \times 1$-column vector. The values $t^2(v)(a)$ and $o^2(v)$ can be computed via matrix multiplication as $T_a \times v$ and $O \times v$.

For a concrete example, consider the weighted automaton $(X, (oX, tX))$ in Fig. 1. The corresponding linear weighted automaton $(\mathbb{R}^X, (o^2, t^2))$ has as state space the space of all the linear combinations of the states in $X$ (i.e., $\{k_1x_1 + k_2x_2 + k_3x_3 \mid k_i \in \mathbb{R}\}$). The function $o^2$ maps $v = k_1x_1 + k_2x_2 + k_3x_3$ into $k_1oX(x_1) + k_2oX(x_2) + k_3oX(x_3)$, i.e., $k_1 + k_2 + k_3$. By exploiting the correspondence between functions and vectors in $\mathbb{R}^X$ (discussed in Section 3.1), we can write $t^2_X(v)(a) = k_1t_X(x_1)(a) + k_2t_X(x_2)(a) + k_3t_X(x_3)(a)$ that is $k_1(x_1 + x_2 + x_3) + k_23x_2 + k_33x_3$ and $t^2_X(v)(b) = k_13x_1 + k_23x_1 + k_33x_3$. This can be conveniently expressed in terms of matrix multiplication:

$$o^2_X(v) = \begin{pmatrix} k_1 \\ k_2 \\ k_3 \end{pmatrix}, \quad t^2_X(v)(a) = \begin{pmatrix} 1 & 0 & 0 \\ 1 & 3 & 0 \\ 1 & 0 & 3 \end{pmatrix} \begin{pmatrix} k_1 \\ k_2 \\ k_3 \end{pmatrix}, \quad t^2_X(v)(b) = \begin{pmatrix} 3 & 3 & 3 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} k_1 \\ k_2 \\ k_3 \end{pmatrix}.$$
A linear map $h: V \rightarrow W$ is an $\mathcal{L}$-homomorphism between $\mathsf{WFA} (V, (o_V, t_V))$ and $(W, (o_W, t_W))$ if the following diagram commutes.

\[
\begin{array}{ccc}
V & \xrightarrow{h} & W \\
\downarrow{\langle o_V, t_V \rangle} & & \downarrow{\langle o_W, t_W \rangle} \\
\mathbb{K} \times V^A & \xrightarrow{id \times h^*} & \mathbb{K} \times W^A
\end{array}
\]

This means that for all $v \in V, a \in A$, $o_V(v) = o_W(h(v))$ and $t_W(h(v))(a) = t_W(h(v))(a)$. If $V$ and $W$ have finite dimension, then we can represent all the morphisms of the above diagram as matrices. In this case, the above diagram commutes if and only if for all $a \in A$,

\[
O_V = O_W \times H \quad \text{and} \quad H \times T_{Va} = T_{Wa} \times H
\]

where $T_{Va}$ and $T_{Wa}$ are the matrix representations of $t_V$ and $t_W$ for any $a \in A$.

For a function $h: X \rightarrow Y$, the function $\mathbb{K}\mathbb{K}^h \cdot \mathbb{K}^X \rightarrow \mathbb{K}^Y$ (formally introduced in Definition 2) is a linear map. Note that if $h$ is a $\mathsf{WFA}$-homomorphism between the $\mathsf{WFA} (X, (o_X, t_X))$ and $(Y, (o_Y, t_Y))$, then $\mathbb{K}^h$ is an $\mathcal{L}$-homomorphism between the $\mathsf{WFA} (\mathbb{K}^X, (o_X^*, t_X^*))$ and $(\mathbb{K}^Y, (o_Y^*, t_Y^*))$. For example, look at the $\mathsf{WFA}$-homomorphism $h: (X, (o_X, t_X)) \rightarrow (Y, (o_Y, t_Y))$ represented by the dashed arrows in Fig. 1. The linear map $\mathbb{K}^h: \mathbb{K}^X \rightarrow \mathbb{K}^Y$ is represented by the matrix $H = (1\ 1\ 1)$ and it is an $\mathcal{L}$-homomorphism between $(\mathbb{K}^X, (o_X^*, t_X^*))$ and $(\mathbb{K}^Y, (o_Y^*, t_Y^*))$. This can be easily checked by showing that $O_X = O_Y \times H$, $H \times T_{Xa} = T_{Ya} \times H$, $H \times T_{Xa} = T_{Ya} \times H$ and $H \times T_{Xa} = T_{Ya} \times H$.

Note that two different weighted automata can represent the same (up to isomorphism) linear weighted automaton. As an example, look at the weighted automata $(X, (o_X, t_X))$ and $(Y, (o_Y, t_Y))$ in Fig. 4. They represent, respectively, the linear weighted automata $(\mathbb{K}^X, (o_X^*, t_X^*))$ and $(\mathbb{K}^Y, (o_Y^*, t_Y^*))$ that are isomorphic. The transitions and the output functions for the two automata are described by the following matrices:

\[
T_{Xa} = \begin{pmatrix} 0 & 0 & 0 \\ 1 & 1 & 0 \\ -1 & 0 & 1 \end{pmatrix}, \quad O_X = (1\ 1\ 1), \quad T_{Ya} = \begin{pmatrix} 3/2 & 0 & 1/2 \\ 1/2 & 1 & 1/2 \\ -3/2 & 0 & -1/2 \end{pmatrix}, \quad O_Y = (2\ 2\ 2).
\]

Note that $T_{Xa}$ and $T_{Ya}$ are similar, i.e., they represent the same linear map. This can be immediately checked by showing that $T_{Ya} = j^{-1} \circ T_{Xa} \circ j$, where $j: \mathbb{K}^Y \rightarrow \mathbb{K}^X$ is the isomorphic map representing the change of bases from $Y = (x_1, x_2, x_3, x_4, x_5)$ to $X = (x_1, x_2, x_3)$ and $j^{-1}: \mathbb{K}^X \rightarrow \mathbb{K}^Y$ is its inverse. The matrix representation of $j$ and $j^{-1}$ is the following:

\[
J = \begin{pmatrix} 1 & 0 & 1 \\ 0 & 1 & 0 \\ 1 & 1 & 0 \end{pmatrix}, \quad J^{-1} = \begin{pmatrix} 1/2 & 1/2 & -1/2 \\ -1/2 & 1/2 & 1/2 \\ 1/2 & -1/2 & 1/2 \end{pmatrix}.
\]

Also $O_X$ and $O_Y$ represent the same map in different bases. Indeed, $O_Y = O_X \times J$.

At this point, it is easy to see that the linear isomorphism $j^{-1}: \mathbb{K}^X \rightarrow \mathbb{K}^Y$ is an $\mathcal{L}$-homomorphism, because $O_X = O_X \times J \circ j^{-1} = O_Y \circ j^{-1}$ and $j^{-1} \times T_{Xa} = j^{-1} \times T_{Ya} = T_{Ya} \times j^{-1}$. Analogously for $j: \mathbb{K}^Y \rightarrow \mathbb{K}^X$.

3.3. Language equivalence and final $\mathcal{L}$-coalgebra

We introduce the final $\mathcal{L}$-coalgebra and we show that the behavioural equivalence $\approx_L$, induced by the functor $\mathcal{L}$, coincides with weighted language equivalence.
Theorem 2 shows that it is final.

Proposition 4 below shows that

Proof. We prove it by induction on $w \in A^*$. The only function making the above diagram commute is $\sigma$, where $\sigma_a : A^* \rightarrow K$ denotes the a-derivative of $\sigma$ that is defined for all $w \in A^*$ as

$$\sigma_0(w) = \sigma(aw).$$

Proposition 3. The maps $\epsilon : K A^* \rightarrow K$ and $d : K A^* \rightarrow (K A^*)^A$ are linear.

Proof. We show the proof for $d$. The one for $\epsilon$ is analogous.

Let $\sigma_1, \sigma_2$ be two weighted languages in $K A^*$. Now for all $a \in A$, $w \in A^*$, $d(\sigma_1 + \sigma_2)(a)(w) = (\sigma_1 + \sigma_2)(aw) = \sigma_1(aw) + \sigma_2(aw) = d(\sigma_1)(a)(w) + d(\sigma_2)(a)(w)$.

Let $k$ be a scalar in $K$ and $\sigma$ be a weighted language in $K A^*$. Now for all $a \in A$, $w \in A^*$, $k \cdot d(\sigma)(a)(w) = k \cdot \sigma(aw) = d(k\sigma)(a)(w)$. □

Since $K A^*$ is a vector space and since $\epsilon$ and $d$ are linear maps, $(K A^*, (\epsilon, d))$ is an $L$-coalgebra. The following theorem shows that it is final.

Theorem 2 (Finality). From every $L$-coalgebra $(V, (o, t))$ there exists a unique $L$-homomorphism into $(K A^*, (\epsilon, d))$.

Proof. The only function making the above diagram commute is $\llbracket - \rrbracket_C$, i.e., the function mapping each vector $v \in V$ into the weighted language that it recognise. Hereafter we show that $\llbracket - \rrbracket_C$ is a linear map.

By induction on $w$, we prove that for all $v_1, v_2 \in V$, for all $w \in A^*$, $\llbracket v_1 + v_2 \rrbracket_C(w) = \llbracket v_1 \rrbracket_C(w) + \llbracket v_2 \rrbracket_C(w)$. Suppose that $w = \epsilon$. Then $\llbracket v_1 + v_2 \rrbracket_C(\epsilon) = o(v_1 + v_2)$. Since $o$ is a linear map, this is equal to $o(v_1) + o(v_2) = \llbracket v_1 \rrbracket_C(\epsilon) + \llbracket v_2 \rrbracket_C(\epsilon)$.

Now suppose that $w = aw'$. Then $\llbracket v_1 + v_2 \rrbracket_C(aw') = \llbracket t(v_1 + v_2)(a) \rrbracket_C(aw')$. Since $t$ is a linear map, this is equal to $\llbracket t(v_1)(a) \rrbracket_C(aw') + \llbracket t(v_2)(a) \rrbracket_C(aw') = \llbracket v_1 \rrbracket_C(aw') + \llbracket v_2 \rrbracket_C(aw')$.

We can proceed analogously for the scalar product. □

Thus, two vectors $v_1$, $v_2 \in V$ are $L$-behaviourally equivalent ($v_1 \approx_C v_2$) iff they recognise the same weighted language (as defined in Section 3.2). Proposition 4 below shows that $\llbracket - \rrbracket_{K_0} : K X_0 \rightarrow K A^*$ is the linearisation of the function $l_X : X \rightarrow K A^*$ (defined in Section 2) or, in other words, is the only linear map making the following diagram commute.

Lemma 1. Let $(X, (o, t))$ be a WA and $(X_0, (o^0, t^0))$ be the corresponding linear weighted automaton. Then for all $x \in X$, $l_X(x) = \llbracket x \rrbracket_{K X_0}$.

Proof. We prove it by induction on $w \in A^*$. If $w = \epsilon$, then $l_X(x)(w) = o_X(x) = \llbracket o_X(x) \rrbracket_{K X_0}(w)$. 
If \( w = aw' \), then \( \llbracket x \rrbracket_{\mathcal{K}_{\omega}^{L}}(w) = \llbracket t^L(x)(a) \rrbracket_{\mathcal{K}_{\omega}^{L}}(w') \). Note that by definition, \( t^L(x)(a) = \sum_{x' \in X} t(x)(a)(x') \cdot x' \) and thus \( \llbracket t^L(x)(a) \rrbracket_{\mathcal{K}_{\omega}^{L}}(w') \) is equal to
\[
\left\{ \sum_{x' \in X} t(x)(a)(x') \cdot x' \right\}_{\mathcal{K}_{\omega}^{L}}(w')
\]
which, by linearity of \( \llbracket - \rrbracket_{\mathcal{K}_{\omega}^{L}} \), coincides with
\[
\sum_{x' \in X} t(x)(a)(x') \cdot \llbracket x \rrbracket_{\mathcal{K}_{\omega}^{L}}(w').
\]
By induction hypothesis \( \llbracket x \rrbracket_{\mathcal{K}_{\omega}^{L}}(w') = I_X(x')(w') \) and thus the above coincides with
\[
\sum_{x' \in X} t(x)(a)(x') \cdot I_X(x')(w')
\]
that is \( I_X(x)(w) \). \( \square \)

**Proposition 4.** Let \((X, (o, t))\) be a WA and \((\mathcal{K}_{\omega}^{L}, (o^L, t^L))\) be the corresponding linear weighted automaton. Then, for all \( v = k_1x_{i_1} + \cdots + k_nx_{i_n}. \) \( [v]_{\mathcal{K}_{\omega}^{L}}^{L} = k_1I_X(x_{i_1}) + \cdots + k_nI_X(x_{i_n}). \)

**Proof.** It follows from Lemma 1 and linearity of \( \llbracket - \rrbracket_{\mathcal{K}_{\omega}^{L}} \). \( \square \)

### 3.4. Linear bisimulations and subspaces

We now introduce a convenient characterisation of language equivalence by means of **linear weighted bisimulations**. Differently from ordinary (weighted) bisimulations, these can be seen both as relations and as subspaces. The latter characterisation will be exploited in the next section for defining an algorithm for checking language equivalence.

First, we show how to represent relations over a vector space \( V \) as subspaces of \( V \), following [40,7].

**Definition 4 (Linear relations).** Let \( U \) be a subspace of \( V \). The binary relation \( R_U \) over \( V \) is defined by
\[
\begin{align*}
    v_1 R_U v_2 & \quad \text{if and only if} \quad v_1 - v_2 \in U.
\end{align*}
\]
A relation \( R \) is **linear** if there is a subspace \( U \) such that \( R \) equals \( R_U \).

Note that a linear relation is a total equivalence relation on \( V \). Let now \( R \) be any binary relation over \( V \). There is a canonical way of turning \( R \) into a linear relation, which we describe in the following. The **kernel** of \( R \) (in symbols \( \ker(R) \)) is the set \( \{ v_1 - v_2 \mid v_1 R v_2 \} \). The **linear extension** of \( R \), denoted \( R^L \), is defined by: \( v_1 R^L v_2 \) if and only if \( (v_1 - v_2) \in \ker(R) \).

**Lemma 2.** Let \( U \) be a subspace of \( V \), then \( \ker(R_U) = U \).

According to the above lemma, a linear relation \( R \) is completely described by its kernel, which is a subspace, that is
\[
\begin{align*}
    v_1 R v_2 & \quad \text{if and only if} \quad (v_1 - v_2) \in \ker(R). \tag{2}
\end{align*}
\]
Conversely, for any subspace \( U \subseteq V \) there is a corresponding linear relation \( R_U \) whose kernel is \( U \). Hence, without loss of generality, we can identify linear relations on \( V \) with subspaces of \( V \). For example, by slight abuse of notation, we can write \( v_1 U v_2 \) instead of \( v_1 R_U v_2 \); and conversely, we will sometimes denote by \( R \) the subspace \( \ker(R) \). The context will be sufficient to tell whether we are actually referring to a linear relation or to the corresponding subspace (kernel). Note that the subspace \([0]\) corresponds to the identity relation on \( V \), that is \( R_{[0]} = \text{Id}_V \). In fact: \( v_1 \text{Id}_V v_2 \) iff \( v_1 = v_2 \) iff \( v_1 - v_2 = 0 \). Similarly, the space \( V \) itself corresponds to \( R_V = V \times V \).

We are now ready to define linear weighted bisimulation. This definition relies on the familiar step-by-step game played on transitions, plus an initial condition requiring that two related states have the same output weight. We call this form of bisimulation linear to stress the difference with the one introduced in Definition 1.

**Definition 5 (Linear weighted bisimulation).** Let \((V, (o, t))\) be a linear weighted automaton. A linear relation \( R \subseteq V \times V \) is a **linear weighted bisimulation** if for all \( (v_1, v_2) \in R \), it holds that:
(1) \(o(v_1) = o(v_2)\),
(2) \(\forall a \in A, t(v_1)(a) R t(v_2)(a)\).

For a concrete example, consider the automaton \((\mathbb{R}^X_{oW}, (o_X, t_X^2))\) in Fig. 4. The relation \(R = \{(x_2, x_3)\}\) is not linear, because \(U = \{x_2 - x_3\}\) is not a subspace of \(\mathbb{R}^X_{oW}\). However, we can turn \(R\) into a linear relation by applying its kernel \(\ker(R) = \{x_2 - x_3\}\). The linear extension of \(R\) is \(R^l = \{(k_1 x_1 + k_2 x_2 + k_3 x_3, k_1' x_1 + k_2' x_2 + k_3' x_3) | k_1 = k_1', k_2 + k_3 = k_2' + k_3'\}\). It is easy to see that \(R^l\) is a linear weighted bisimulation.

The following lemma provides a characterisation of linear weighted bisimulation as a subspace. Let us say that a subspace \(V\) is \(f\)-invariant if \(f(U) \subseteq U\). Bisimulations are transition-invariant relations that refine the kernel of the output map \(o\).

**Lemma 3.** Let \((V, (o_V, t_V))\) be an LWA and \(R\) be a linear relation over \(V\). \(R\) is a linear weighted bisimulation if and only if
(1) \(R \subseteq \ker(o)\),
(2) \(R\) is \(t_v\)-invariant for each \(a \in A\).

This lemma will be fundamental in the next section for defining an algorithm computing the greatest linear weighted bisimulation and, vice versa, for each linear weighted bisimulation \(R\) there exists an \(L\)-homomorphism whose kernel is \(R\).

**Proposition 5.** Let \((V, (o_V, t_V))\) be an LWA. If \(f : V \rightarrow W\) is an \(L\)-homomorphism (for some LWA \((W, (o_W, t_W))\)) then \(\ker(f)\) is a linear weighted bisimulation. Conversely, if \(R\) is a linear weighted bisimulation for \((V, (o, t))\), then there exist an LWA \((W, (o_W, t_W))\) and an \(L\)-homomorphism \(f : V \rightarrow W\) such that \(\ker(f) = R\).

**Proof.** First, we suppose that \(f : V \rightarrow W\) is an \(L\)-homomorphism and we prove that \(\ker(f)\) satisfies (1) and (2) of Lemma 3. Take a vector \(v \in \ker(f)\). Thus, \(f(v) = 0\) and, since \(o_W\) and \(t_W\) are linear maps, \(o_W(f(v)) = 0\) and \(t_W(f(v))(a) = 0\) for all \(a \in A\). Since \(f\) is an \(L\)-homomorphism, we have that (1) \(o_W(v) = o_W(f(v)) = 0\), i.e., \(\ker(f) \subseteq \ker(o)\) and (2) \(f(t_W(v)(a)) = t_W(f(v))(a) = 0\) meaning that \(t_V(f(v))(a) \in \ker(f)\), i.e., \(\ker(f)\) is \(t_v\)-invariant.

In order to prove the second part, we need to recall quotient spaces and quotient maps from [18]. Given a subspace \(U\) of \(V\), the equivalence class of \(v\) w.r.t. \(U\) is \([v]_U = \{v + u | u \in U\}\). Note that \(v_1 \in [v_2]_U\) if and only if \(v_1 R_U v_2\). The quotient space \(V/U\) is the space of all equivalence classes \([v]\) where scalar product \(k[v]\) is defined as \([kv]\) and the sum \([v_1]_U + [v_2]_U\) as \([v_1 + v_2]_U\). It is easy to check that these operations are well-defined (i.e., independent from the choice of the representative) and turn \(V/U\) into a vector space where the element 0 is \(U\). Most importantly, the quotient function \(\epsilon_U : V \rightarrow V/U\) mapping each vector \(v\) into \([v]_U\) is a linear map such that \(\ker(\epsilon_U) = U\).

Now, let \(U\) be the subspace corresponding to the linear weighted bisimulation \(R\). We can take \(W = V/U\) and we define \(o_W\) as \(o_W([v]_U) = o_V(v)\) and \(t_W\) as \(t_W([v]_U)(a) = [t_V(v)(a)]_U\). Note that both \(o_W\) and \(t_W\) are well-defined: for all \(v' \in [v]_U = \{v + u | u \in U\}\), \(o_W(v') = o_W(v)\) (since \(o_V(u) = 0\) for all \(u \in U\)) and \(t_W(v')(a) \in [t_W(v)(a)]_U\). It is also easy to check that they are linear.

Finally, we take \(f : V \rightarrow W\) as \(\epsilon_U\) and with the previous definition of \(o_W\) and \(t_W\) is trivial to check that \(\epsilon_U\) is an \(L\)-homomorphism. As said above, its kernel is \(U\).

**Theorem 3.** Let \((V, (o, t))\) be an LWA and let \([-[-1]_F^2 : V \rightarrow \mathbb{K}^A^*\) be the unique \(L\)-morphism into the final coalgebra. Then \(\ker([-[-1]_F^2)\)

is the largest linear weighted bisimulation on \(V\).

**Proof.** First of all, note that by the first part of Proposition 5, \(\ker([-[-1]_F^2)\) is a linear weighted bisimulation.

Now, suppose that \(R\) is a linear weighted bisimulation. By the second part of Proposition 5, there exist an LWA \((W, (o_W, t_W))\) and an \(L\)-homomorphism \(f : V \rightarrow W\) such that \(R = \ker(f)\). Now note that, since \((W, (o_W, t_W))\) is an \(L\)-coalgebra there exists an \(L\)-homomorphism \([-[-1]_W^2 : W \rightarrow \mathbb{K}^A^*\) to the final coalgebra. Since the composition of two \(L\)-homomorphisms is still an \(L\)-homomorphism, also \([-[-1]_W^2 \circ f : V \rightarrow \mathbb{K}^A^*\) is an \(L\)-homomorphism. Since \([-[-1]_W^2 is the unique \(L\)-homomorphism from \(V\) to \(\mathbb{K}^A^*\), then \([-[-1]_W^2 \circ f = [-[-1]_F^2). Finally, \(R = \ker(f) \subseteq \ker([-[-1]_W^2 \circ f) = \ker([-[-1]_F^2)\).

**Corollary 1.** \(\approx_L\) is the largest linear weighted bisimulation.

The characterisation of bisimulations as subspaces seems to be possible in Vect and not in Set because the former category is abelian [13]: every map has a kernel that is a subspace and every subspace is the kernel of some map. We leave as future work to study (at a more general level) the categorical machinery allowing to characterise bisimulations as subspaces.

In Section 2, we have shown that the largest linear weighted bisimulation \((\sim_w)\) is strictly included in language equivalence, while here we have shown that the largest linear weighted bisimulation coincides with language equivalence. However, it
is not clear yet what is the relationship between weighted bisimulations and linear weighted bisimulations. The following proposition explains it.

**Proposition 6.** Let $(X, (o, t))$ be a weighted automaton and $(K^X_{ω_o}, (o^X, t^X))$ be the corresponding linear weighted automaton. If $R$ is a weighted bisimulation on $X$, then $R^*$ is a linear weighted bisimulation on $K^X_{ω_o}$.

**Proof.** Recall the weighted automaton $(X/R, (o_{X/R}, t_{X/R}))$ and the function $e_R : X \rightarrow X/R$ defined before Theorem 1 and recall also that $e_R$ is a $\mathcal{V}$-homomorphism between $(X, (o, t))$ and $(X/R, (o_{X/R}, t_{X/R}))$. In Section 3.2, we have shown that, for every $\mathcal{V}$-homomorphism $h$, $K^h_{ω_o}$ is an $\mathcal{L}$-homomorphism. Therefore $K^h_{ω_o} : K^X_{ω_o} \rightarrow K^{X/R}_{ω_o}$ is an $\mathcal{L}$-homomorphism between $(K^X_{ω_o}, (o^X, t^X))$ and $(K^{X/R}_{ω_o}, (o^{X/R}, t^{X/R}))$. By Proposition 5, $\ker(K^h_{ω_o})$ is a linear weighted bisimulation on $K^X_{ω_o}$.

Therefore, in order to complete the proof, we only have to prove that $\ker(K^h_{ω_o}) = R^*$. First of all note that $K^h_{ω_o} : K^X_{ω_o} \rightarrow K^{X/R}_{ω_o}$ maps each $v = k_1 x_1 + \cdots + k_n x_n$ in

$$\sum_{[x_i]_R \in X/R} \left( \sum_{j \in [k_j]_R} k_j \right) [x_i]_R$$

and thus $v \in \ker(K^h_{ω_o})$ if and only if for all $x_i$, $\sum_{j \in [k_j]_R} k_j = 0$. Then, we show that $v \in R^*$ if and only if the same condition holds. Indeed, by definition, $v \in R^*$ if and only if for all $j, l \in \{1, \ldots, n\}$, exist $k_{j,l}$ such that (1) $v = \sum_{j=1}^n \sum_{l=1}^n k_{j,l}(k_j - k_l)x_i$ and (2) if $(x_j, x_l) \notin R$ then $k_{j,l} = 0$. Thus

$$v = \sum_{i=1}^n (k_{i,1} - k_{i,1}^*) x_1 + \cdots + \sum_{i=1}^n (k_{i,n} - k_{i,n}) x_n,$$

i.e., for all $j$, $k_j = \sum_{i=1}^n (k_{j,i} - k_{j,i}^*)$. Recall that, according to Definition 1, $R$ is an equivalence relation and thus $(x_j, x_l) \in R$ if and only if $x_j = [x_i]_R$. Then, by (2) above, $k_j = \sum_{i \in [x_i]_R} (k_{j,i} - k_{j,i}^*)$. For all $x_i$, $\sum_{j \in [k_j]_R} k_j = \sum_{j \in [k_j]_R} \sum_{i \in [x_i]_R} (k_{j,i} - k_{j,i}^*)$. Since $[x_j]_R = [x_i]_R$, each $k_{j,i}$ occurs exactly once in a positive way and once in a negative way and thus $\sum_{j \in [k_j]_R} k_j = 0$. $\square$

The other implication does not hold. For instance, there exists no weighted bisimulation relating the states $y_1$ and $z_1$ in Fig. 2, however we can show a linear weighted bisimulation relating them: the linear extension of $R = \{(y_1, z_1), (y_2, z_2), (y_3 + y_5, 2z_3)\}$ is a linear weighted bisimulation.

4. Linear partition refinement

In the previous section, we have shown that weighted language equivalence ($\sim_\gamma$) can be seen as the largest linear weighted bisimulation. In this section, we exploit this characterisation in order to provide a "partition-refinement" algorithm that allows to compute $\gamma$. We will examine below two versions of this algorithm, a forward version (Section 4.1) and a backward one (Section 4.2). The former is straightforward but computationally not very convenient; the latter is more convenient, although it requires the introduction of some extra machinery. In both cases, we must restrict to tWA’s where the state space is of finite dimension.

4.1. A forward algorithm

Lemma 3 suggests that, in order to compute the largest linear weighted bisimulation for an tWA $(V, (o, t))$, one might start from $\ker(o)$ and refine it until the condition (2) given in the lemma is satisfied. This is indeed the case.

**Proposition 7 (Partition refinement, forward version).** Let $(V, (o, t))$ be an tWA. Consider the sequence $(R_i)_{i \geq 0}$ of subspaces of $V$ defined inductively by

$$R_0 = \ker(o), \quad R_{i+1} = R_i \cap \bigcap_{a \in A} t(R_i)(a)^{-1}$$

where $t(R_i)(a)^{-1}$ is the space $\{v \in V \mid t(v)(a) \in R_i\}$. Then there is $j \leq \dim(V)$ such that $R_{j+1} = R_j$. The largest linear weighted bisimulation is $\approx_\mathcal{L} = R_j$.

**Proof.** The $R_i$‘s form a descending chain of subspaces of $V$. The corresponding dimensions form a non-increasing sequence, hence the existence of $j$ as required is obvious. That $R_j$ is a bisimulation follows by applying Lemma 3: indeed, it is obvious that (1) $\ker(o) \supseteq R_j$, while as to (2) we have that, since $R_{j+1} = R_j$, then $R_j \cap \bigcap_{a \in A} t(R_j)(a)^{-1} = R_j$, i.e., for all $a \in A$, $t(R_j)(a) \subseteq R_j$. 

We finally show that any linear weighted bisimulation \( R \) is included in \( R_j \). We do so by proving that for each \( i, R \subseteq R_i \), thus, in particular \( R \subseteq R_j \). We proceed by induction on \( i \). Again by Lemma 3, we know that \( R_0 = \ker(o) \supseteq \ker(v) \). Assume now \( R \subseteq R_i \). For each action \( a \), by Lemma 3 we have that \( t(R)(a) \subseteq \ker(v) \), which implies \( R \subseteq [v \in R_i \mid \forall a \in A, t(v)(a) \in R_i] = R_{i+1} \).

Concretely, the algorithm iteratively computes a basis \( B_i \) for each space \( R_i \). This can be done by solving systems of linear equations expressing the constraints in the definition of \( R_i \). Since the backward algorithm presented in the next section is computationally more efficient, we avoid to give further details about its implementation and we show, as an example, the algorithm at work with the linear automata \( (V, (o, t)) \) in Fig. 5.

**Example 1.** We start by computing a basis for \( R_0 = \ker(o) \). This is

\[
B_0 = \left\{ \begin{pmatrix} -\frac{1}{2} \\ 1 \\ 0 \end{pmatrix}, \begin{pmatrix} -\frac{1}{2} \\ 0 \\ 1 \end{pmatrix} \right\}.
\]

In the first iteration, we compute one basis for the space \( t(R_0)(a)^{-1} \) and one for the space \( t(R_0)(b)^{-1} \). These are respectively

\[
B_1^a = \left\{ \begin{pmatrix} -\frac{1}{3} \\ 1 \\ 0 \end{pmatrix}, \begin{pmatrix} -1 \\ 0 \\ 1 \end{pmatrix} \right\} \quad \text{and} \quad B_1^b = \left\{ \begin{pmatrix} -\frac{5}{6} \\ 1 \\ 0 \end{pmatrix}, \begin{pmatrix} -\frac{3}{2} \\ 0 \\ 1 \end{pmatrix} \right\}.
\]

Then, \( R_1 \) is given by the intersection \( R_0 \cap t(R_0)(a)^{-1} \cap t(R_0)(b)^{-1} \). A basis for \( R_1 \) is

\[
B_1 = \left\{ \begin{pmatrix} -2 \\ 3 \\ 1 \end{pmatrix} \right\}.
\]

In the second iteration, we compute one basis for the space \( t(R_1)(a)^{-1} \) and one for the space \( t(R_1)(b)^{-1} \). These are respectively

\[
B_2^a = \left\{ \begin{pmatrix} -\frac{1}{3} \\ 1 \\ 0 \end{pmatrix}, \begin{pmatrix} -1 \\ 0 \\ 1 \end{pmatrix} \right\} \quad \text{and} \quad B_2^b = \left\{ \begin{pmatrix} -2 \\ 3 \\ 1 \end{pmatrix} \right\}.
\]

Then, \( R_2 \) is the intersection \( R_1 \cap t(R_1)(a)^{-1} \cap t(R_0)(b)^{-1} \). A basis for \( R_2 \) is

\[
B_2 = \left\{ \begin{pmatrix} -2 \\ 3 \\ 1 \end{pmatrix} \right\}
\]

that is equal to \( B_1 \). Since \( R_1 = R_2 \) the algorithm terminates and returns \( R_1 \). Now, in order to check if two vectors \( v_1, v_2 \in V \) accept the same weighted language (i.e., \( v_1 \approx L v_2 \)), we have to look if \( v_1 - v_2 \) belongs to \( R_1 \). For instance, \( x_1 \approx L \frac{7}{2} x_2 + \frac{1}{2} x_3 \) because \( x_1 - \frac{7}{2} x_2 - \frac{1}{2} x_3 \in R_1 \).

We note that \( \ker(o) \) is in general a large subspace: since \( o : V \to \mathbb{K} \) with \( \dim(\mathbb{K}) = 1 \), by virtue of Eq. (1) we have that \( \dim(\ker(o)) \geq \dim(V) - 1 \). This might be problematic in the actual computation of the basis of \( \approx_L \). We present an alternative version in the next subsection which will avoid this problem.

**Fig. 5.** A weighted automata \( (V, (o, t)) \) (left) and its reversed \( (V, (o, t^t)) \) (right).
4.2. A backward algorithm

Two well-known concepts from linear algebra will be relied upon to describe the basic operations of the backward algorithm. More precisely, annihilators will be used to describe the complement of a relation, while transpose maps will be used to describe the operation of “reversing arrows” in an automaton. These operations are carried out within the dual space of V. So we start by reviewing the concept of dual space; an in-depth treatment can be found in e.g. [18].

Let K be any field and V a vector space over K. The dual space of V, denoted V*, is the set of all linear maps V → K, with K seen as a 1-dimensional vector space. The elements of V* are often called functionals and we use ψ, ψ2, . . . to range over them. The sum of two functionals ψ1 + ψ2 and the scalar multiplication k · ψ (for k ∈ K) are defined point-wise as expected, and turn V* into a vector space over K. We will denote functional application ψ(v) as [v, ψ], the bracket notation intending to emphasise certain analogies with inner products. Fix an ordered basis B = (v1, . . . , vn) of V and consider B* = (v1*, . . . , vn*), where the functionals vj* are specified by [vj, vj*] = δij for each i and j. Here, δij denotes the Kronecker symbol, which equals 1 if i = j and 0 otherwise. It is easy to check that B* forms a basis of V*, referred to as the dual basis of B. Hence dim(V*) = dim(V). In particular, the morphism (−)∗ : V → V* that sends each vj into vj* is an isomorphism between V and V*. A crucial definition is that of transpose morphism.

Definition 6 (Transpose linear map). Let f : V → V be a linear map. We let the transpose of f be the endomorphism f : V* → V* defined for all ψ ∈ V* as f(ψ) = ψ ◦ f.

It is easy to check that if F is the matrix representing f in V w.r.t. to B, then the transpose matrix F represents f in V* w.r.t. B*, whence the terminology and the notation. Denote by V** the space (V*)*, called double dual of V. There is a natural isomorphism i between V and V**, given by i : v → [v, −] (note that this isomorphism does not depend on the choice of a basis). In the sequel, we shall freely identify V and V** up to this isomorphism, i.e. identify v and [v, −] for each v ∈ V. With this identification, one has that i(f) = f.

We need another concept from duality theory. Given a subspace U of V, we denote by U0 the annihilator of U, the subset of functionals that vanish on U.

Definition 7 (Annihilator). For any subspace U ⊆ V, we let U0 = {ψ ∈ V* | [u, ψ] = 0 for each u ∈ U}.

Once again, the notation makes the analogy with inner products explicit. We use the following properties of annihilators, where U, W are subspaces of V: (i) U0 is a subspace of V*; (ii) (−)0 reverses inclusions, i.e. if U ⊆ W then W0 ⊆ U0; (iii) (−)0 is an involution, that is (U0)0 = U up to the natural isomorphism between V and its double dual. These three properties suggest that U0 can be regarded as a complement, or negation, of U seen as a relation. Another useful property is: (iv) dim(U0) + dim(U) = dim(V). Transpose morphisms and annihilators are connected via the following property, which is crucial to the development of the algorithm. It basically asserts that f-invariance of R corresponds to f-invariance of the complementary relation represented by R0.

Lemma 4. Let U be a subspace of V and f be an endomorphism on V. If U is f-invariant then U0 is f-invariant.

We are now ready to give the backward version of the partition-refinement algorithm. An informal preview of the algorithm is as follows. Rather than computing directly the subspace representing a relation, while transpose maps will be used to describe the operation of “reversing arrows” in an automaton. These operations are carried out within the dual space of V. So we start by reviewing the concept of dual space; an in-depth treatment can be found in e.g. [18].

Let K be any field and V a vector space over K. The dual space of V, denoted V*, is the set of all linear maps V → K, with K seen as a 1-dimensional vector space. The elements of V* are often called functionals and we use ψ, ψ2, . . . to range over them. The sum of two functionals ψ1 + ψ2 and the scalar multiplication k · ψ (for k ∈ K) are defined point-wise as expected, and turn V* into a vector space over K. We will denote functional application ψ(v) as [v, ψ], the bracket notation intending to emphasise certain analogies with inner products. Fix an ordered basis B = (v1, . . . , vn) of V and consider B* = (v1*, . . . , vn*), where the functionals vj* are specified by [vj, vj*] = δij for each i and j. Here, δij denotes the Kronecker symbol, which equals 1 if i = j and 0 otherwise. It is easy to check that B* forms a basis of V*, referred to as the dual basis of B. Hence dim(V*) = dim(V). In particular, the morphism (−)∗ : V → V* that sends each vj into vj* is an isomorphism between V and V*. A crucial definition is that of transpose morphism.

Definition 6 (Transpose linear map). Let f : V → V be a linear map. We let the transpose of f be the endomorphism f : V* → V* defined for all ψ ∈ V* as f(ψ) = ψ ◦ f.

It is easy to check that if F is the matrix representing f in V w.r.t. to B, then the transpose matrix F represents f in V* w.r.t. B*, whence the terminology and the notation. Denote by V** the space (V*)*, called double dual of V. There is a natural isomorphism i between V and V**, given by i : v → [v, −] (note that this isomorphism does not depend on the choice of a basis). In the sequel, we shall freely identify V and V** up to this isomorphism, i.e. identify v and [v, −] for each v ∈ V. With this identification, one has that i(f) = f.

We need another concept from duality theory. Given a subspace U of V, we denote by U0 the annihilator of U, the subset of functionals that vanish on U.

Definition 7 (Annihilator). For any subspace U ⊆ V, we let U0 = {ψ ∈ V* | [u, ψ] = 0 for each u ∈ U}.

Once again, the notation makes the analogy with inner products explicit. We use the following properties of annihilators, where U, W are subspaces of V: (i) U0 is a subspace of V*; (ii) (−)0 reverses inclusions, i.e. if U ⊆ W then W0 ⊆ U0; (iii) (−)0 is an involution, that is (U0)0 = U up to the natural isomorphism between V and its double dual. These three properties suggest that U0 can be regarded as a complement, or negation, of U seen as a relation. Another useful property is: (iv) dim(U0) + dim(U) = dim(V). Transpose morphisms and annihilators are connected via the following property, which is crucial to the development of the algorithm. It basically asserts that f-invariance of R corresponds to f-invariance of the complementary relation represented by R0.

Lemma 4. Let U be a subspace of V and f be an endomorphism on V. If U is f-invariant then U0 is f-invariant.

We are now ready to give the backward version of the partition-refinement algorithm. An informal preview of the algorithm is as follows. Rather than computing directly the subspace representing ≈L, the algorithm computes the subspace representing the complementary relation. To this end, the algorithm starts from a relation R0 that is the complement of the relation identifying vectors with equal weights, then incrementally computes the space of all states that are backward reachable from R0. The largest bisimulation is obtained by taking the complement of this space. Geometrically, “going backward” means working with the transpose function 1t on R rather than with t. Taking the complement of a relation actually means taking its annihilator. This essentially leads one to work within V* rather than V. Recall that U + W denotes span(U ∪ W).

Theorem 4 (Partition refinement, backward version). Let (V, (o, t)) be an LWA. Consider the sequence (Ri)i≥0 of subspaces of V* inductively defined by:

\[ R_0 = \ker(o^0), \quad R_{i+1} = R_i + \sum_{a \in A} 1_{t_a}(R_i). \]  

Then there is j ≤ dim(L) such that Rj+1 = Rj. The largest L-bisimulation ≈L is Rj0, modulo the natural isomorphism between V and V**.

Proof. Since R0 ⊆ R1 ⊆ R2 ⊆ ⋯ ⊆ V*, the sequence of the dimensions of these spaces is non-decreasing. As a consequence, for some j ≤ dim(V*) = dim(L), we get dim(Rj) = dim(Rj+1). Since Rj ⊆ Rj+1, this implies Rj = Rj+1.
We next show that $R_j^0$ is an $L$-bisimulation. Indeed, by the properties of annihilators and up to the natural isomorphism:

1. $\ker(o^0) \subseteq R_j$ implies $(\ker(o^0)^o)^o = \ker(o) \supseteq R_j^0$. Moreover: (2) for any $a \in A$, $t_a(R_j) \subseteq t_a(R_j) + R_j \subseteq R_{j+1} = R_j$ implies, by Lemma 4, that $(t_a(R_j) + R_j)^0 \subseteq R_j^0$; by (1), (2) and Lemma 3, we conclude that $R_j^0$ is an $L$-bisimulation.

We finally show that any $L$-bisimulation $R$ is included in $R_j^0$. We do so by proving that for each $i$, $R \subseteq R_j^0$, thus, in particular $R \subseteq R_j$. We proceed by induction on $i$. Again by Lemma 3, we know that $R_j^0 = \ker(o) \supseteq R$. Assume now $R \subseteq R_j^0$, that is, $R_j \subseteq R_j^0$. For each action $a$, by Lemma 3 we have that $t_a(R_j) \subseteq R_j$, which implies $t_a(R_j) \supseteq R_j^0$ by Lemma 4. Hence $R_j^0 \supseteq t_a(R_j)^0 \supseteq t_a(R_j)$, where the last inclusion stems from $R_j^0 \supseteq R_j$. Since this holds for each $a$, we have that $R_j^0 \supseteq \sum_a t_a(R_j) + R_j = R_{j+1}$. Taking the annihilator of both sides reverses the inclusion and yields the wanted result. \hfill \Box

We note that what is being “refined” in the algorithm above are not, of course, the subspaces $R_j$, but their complements: $R_j^0 \supseteq R_j^0 \supseteq \cdots \supseteq R_j^0 = \approx_{L^o}$.

In particular, we start with a “small” space $R_j^0$ of dimension $\leq 1$: this may represent an advantage in a practical implementation of the algorithm.

To conclude the section, we briefly discuss some practical aspects involved in the implementation of the algorithm. By virtue of (2), checking $v_1 \approx_{L^o} v_2$, for any pair of vectors $v_1$ and $v_2$, is equivalent to checking $v_1 - v_2 \in \ker(\approx_{L^o})$. This can be done by first computing a basis of $\approx_{L^o}$ and then checking for linear (in)dependence of $v_1 - v_2$ with respect to this basis. Alternatively, and more efficiently, one can check whether $v_1 - v_2$ is in $R_j^0$, or, more explicitly, whether $[v_1 - v_2, \psi] = 0$ for each $\psi \in R_j$. This reduces to showing whether $[v_1 - v_2, \psi] = 0$ for each $\psi \in R_j$, where $B_j$ is a basis for $R_j$. Thus, our task reduces to computing such a basis. To do so, fix any basis $B$ of $V$ and let $O \subseteq B (a \in A)$ be the row vectors and matrices, respectively, representing the weight function $o$ and transition functions $T_a$ of the LWA in the basis $B$. The concrete computations are carried out representing vectors and functionals in this basis.

1. Compute a basis $B_0 = B_0$. As already discussed, dim($\ker(o)$) $\leq$ dim($V$) $- 1$, hence dim($\ker(o)^o$) $\leq 1$. It is readily checked that $o \in \ker(o)^o$, thus $\ker(o)^o$ is spanned by $o$. We thus set $B_0 = \{o\}$. With respect to the chosen basis $B$, $B_0$ is represented by $B$.

2. For each $i \geq 0$, compute a basis $B_{i+1}$ of $R_{i+1}$. This can be obtained by incrementally joining to $B_j$ the functionals $t_a(\psi)$, for $a \in A$ and $\psi \in B_j$, that are linearly independent from previously joined functionals. With respect to the basis $B$, $t_a(\psi)$ is represented by $\Psi \times T_a$, where $\Psi$ is the row vector representing $\psi$: checking linear independence of $t_a(\psi)$ means hence checking linear independence of $\Psi \times T_a$ from previously joined row vectors.

After $j \leq n$ iterations, one finds a set $B_j$ such that $B_{j+1} = B_j$: this is the basis of $R_j$. We illustrate this algorithm in the example below.

**Example 2.** Consider the LWA $(V, (o, t))$ on the left of Fig. 5. At the beginning we can set $B_0 = \{o\}$. Next, we apply the algorithm to build the $B_j$'s. Manually, the computation of the vectors $\Psi \times T_a = t_a(\Psi \times T_a)$ can be carried out by looking at the transitions of the wa with arrows reversed (in the right of Fig. 5). Doing so, we first get $O \times T_a = (2 \frac{1}{2} \ 2)$ and $O \times T_b = (2 \frac{1}{2} \ 3)$. Note that $O \times T_b$ is not linearly independent from the other vectors: $O \times T_b = -(2 \ 1 \ 1) + 2(2 \frac{1}{2} \ 2)$. Thus $B_1 = \{(2 \ 1 \ 1), (2 \frac{1}{2} \ 2)\}$. In the second iteration, we compute $(2 \frac{1}{2} \ 2) \times T_a = (2 \frac{1}{2} \ 2)$ and $(2 \frac{1}{2} \ 2) \times T_b = (2 \frac{1}{2} \ 2)$ and thus $B_2 = \{(2 \ 1 \ 1), (2 \frac{1}{2} \ 2)\}$ that is equal to $B_1$.

The functionals represented by vectors in $B_1$ are a basis of $(\approx_{L^o})^o$. As an example, let us check that $x_1 \approx_{L^o} \frac{3}{2}x_2 + \frac{1}{2}x_3$. To this purpose, note that the difference vector $x_1 - \frac{3}{2}x_2 - \frac{1}{2}x_3$ annihilates $B_1$, that is

$$\begin{bmatrix} 1 \\ -\frac{3}{2} \\ -\frac{1}{2} \end{bmatrix} \cdot u = 0$$

for each $u \in B_1$, which is equivalent to $x_1 \approx_{L^o} \frac{3}{2}x_2 + \frac{1}{2}x_3$.

It is quite easy to give an upper bound on the cost of the backward algorithm, in terms of the number of required elementary operations, that is sum and product operations in the underlying field.

A first, crude analysis is as follows. Let $n$ be the dimension of $V$. Each time we join a new vector $v = \Psi \times T_a$ to the basis $B$, we have a cost of $O(n^2)$ for vector–matrix multiplication, plus a cost of $O(n^3)$ for checking linear independence of $v$ from $B$, for a predominant cost of $O(n^2)$. Since the operation of joining a vector to the basis cannot be done more than $n$ times, we have a global cost of $O(n^3)$.

In fact, this complexity can be improved if we maintain the vectors in the basis $B$ in canonical echelon form: this means that, as columns, they can be arranged to form a matrix that can be augmented so as to become a lower triangular matrix with 1 on the main diagonal (in other words, the first nonzero entry from the top of any column is 1 and lies below the first nonzero entry of the column on its left). Checking that any vector $v$ is linearly independent from $B$ can be done solving a system of $n$ equations with $k$ unknowns, where $k$ is the current cardinality of $B$: exploiting the echelon canonical form of $B$ and using Gaussian elimination, this costs $O(kn)$ operations. Moreover, in case $v$ is linearly independent from $B$,
we can compute a new vector $v'$ such that span($B \cup \{v'\}$) = span($B \cup \{v\}$) and $B \cup \{v'\}$ is still in canonical echelon form; this $v'$, rather than $v$, is therefore joined to $B$. Using elementary linear algebra (see e.g. [36]), the computation of $v'$ can be done using again $O(kn)$ operations. This modification takes the overall complexity of the algorithm to $O(n^3)$. This matches the complexity of Schützenberger's original minimisation algorithm, as analysed e.g. by Sakarovitch in [10, Chapter 4]. This algorithm can also be used for deciding equality between two recognisable formal power series.

4.3. The final sequence and the forward algorithm

The theory of coalgebras also provides a way of constructing final coalgebras by means of final sequences (often referred to in the literature as terminal sequences) [4]. Many important algorithms for computing behavioural equivalences (such as [22]) can be abstractly described in terms of final sequences.

In this section, we describe the relationship between the forward algorithm (in Proposition 7) and the final sequence of the functor $L$. The latter is the cochain

$$1 \xleftarrow{L} 1 \xleftarrow{L^2} 1 \xleftarrow{L^n} \ldots$$

where $L^{n+1}$ is $L \circ (L^n)$, $L^0 1 = 1$ is the final vector space $[0]$, and $1$ is the unique morphism from $L$ to $1$.

Let $A^*_n$ be the set of all words $w \in A^*$ with length smaller than $n$. For each $n$, $L^n 1$ is isomorphic to $\mathbb{K}^A_n$, i.e., the space of functions from $A^*_n$ to $\mathbb{K}$. Indeed, for $n = 1$, $L 1$ is by definition $\mathbb{K} \times A = \mathbb{K}$ that is isomorphic to the space of functions from $A^*_1 = \{e\}$ to $\mathbb{K}$; and for $n + 1$, each $(k, \sigma) \in \mathbb{K} \times L^n(A) = L^{n+1} 1$ can be seen as a function $A^* \rightarrow \mathbb{K}$ mapping $e$ into $k$ and $aw$ (for $a \in A$ and $w \in A^*_n$) into $\sigma(a)(w)$.

For $\sigma : A^*_n \rightarrow \mathbb{K}$ and $n \leq m$, the $n$-restriction of $\sigma$ is $\sigma|_n : A^*_n \rightarrow \mathbb{K}$ defined as $\sigma$, but in a restricted domain. The morphism $L^m : L^{n+1} \rightarrow L^n 1$ maps each $\sigma$ into $\sigma|_n$.

The limit of this cochain is $\mathbb{K}^A$ together with the maps $\zeta_n : \mathbb{K}^A \rightarrow L^n 1$ that assign to each weighted language $\sigma$ its $n$-restriction $\sigma|_n$.

$$1 \xleftarrow{L} 1 \xleftarrow{L^2} 1 \xleftarrow{L^n} \mathbb{K}^A \xleftarrow{\zeta_n} L^n 1 \xleftarrow{\ldots}$$

Every $L$-coalgebra $(V, (o, t))$ defines a cone $!^n : V \rightarrow L^n 1$ as follows:

- $!^0 : V \rightarrow 1$ is the unique morphism to the final vector space 1,
- $!^{n+1} : V \rightarrow L^{n+1} 1 = L((!^n) \circ (o, t))$.

The latter can be more concretely defined for all $v \in V$ and $w \in \mathbb{K}^A_{n+1}$ as

$$!^{n+1}(v)(w) = \begin{cases} o(v), & \text{if } w = e; \\ !^n(t(v)(a))(w'), & \text{if } w = aw'. \end{cases}$$

Note that the final morphism $[-]_V : V \rightarrow \mathbb{K}^A$ (mapping each $v \in V$ in the language that it recognises) is the unique function such that for all $n$, $\zeta_n \circ [-]_V = !^n$.

Recall that the $L$-behavioural equivalence on $(V, (o, t))$ is the kernel of $[-]_V$. The forward algorithm computes it, by iteratively computing the kernel of the morphisms $!^n$.

**Proposition 8.** Let $(V, (o, t))$ be an LWA. Let $R_n$ be the relation computed by the forward algorithm (Proposition 7). Let $!^n : V \rightarrow L^n 1$ be the morphisms described above. Then for all natural numbers $n$, $R_n = \ker(!^{n+1})$.

**Proof.** First of all, note that the kernel of $!^0 : V \rightarrow 1$ is the whole $V$. The kernel of $!^{n+1}$ is the space composed of those $v \in V$ such that $!^{n+1}(v)(w) = 0$ for all the words $w \in A^*_n$, i.e.,

$$\ker(!^{n+1}) = \{ v \in V \mid o(v) = 0 \text{ and } \forall a \in A, t(v)(a) \in \ker(!^n) \}.$$

By induction on $n$, we prove that $\ker(!^{n+1}) = R_n$.

For $n = 0$, note that $\ker(!^0) = \{ v \in V \mid o(v) = 0 \text{ and } \forall a \in A, t(v)(a) \in \ker(!_0) \}$. Since $\ker(!^0) = V$, $\ker(!^1) = \{ v \in V \mid o(v) = 0 \} = R_0$. 

Author's personal copy
As induction hypothesis suppose that \( \ker(t^k) = R_{n-1} \). Then \( \ker(t^{k+1}) = \{ v \in V \mid o(v) = 0 \} \) and \( \forall a \in A. \ t(v)(a) \in R_{n-1} \) \( \Rightarrow \) \( R_{n} \). 

This result can be seen as an alternative proof of the soundness of the forward algorithm. Indeed, if \( R_j \) is the result of the algorithm, for all \( k \geq j \), \( R_k = R_j \), i.e., \( \ker(t^k) = \ker(t^j) \). Thus \( R_j = \bigcap_n \ker(t^n) \) and, by definition of \( t^n \), \( \bigcap_n \ker(t^n) = \ker(\lceil \cdot \rceil^j) \).

5. Weighted languages and rationality

We recall from Section 3 that a linear weighted automaton \( (lwa) \) is a coalgebra for the functor \( L = \mathbb{K} \times \mathbb{A} \), i.e., it consists of a vector space \( V \) and a linear map \( (o, t) : V \to \mathbb{K} \times V \mathbb{A} \). We saw in Theorem 2 that the final homomorphism \( [-] : V \to \mathbb{K}^A \) maps every vector \( v \in V \) to the weighted language \( [v]_L \) that is accepted by \( v \). Moreover, the kernel of this morphism is weighted language equivalence \( (\cong_L) \) that, when \( V \) is finite dimension, can be computed via the linear partition-refinement algorithm (shown in Section 4).

The languages in \( \mathbb{K}^A \) that are accepted by \( lwa \) with finite dimension state spaces are called rational weighted languages (which are also known as rational formal power series) and they can be syntactically represented by a language of expressions [38,33].

In this section, we shall directly characterise \( [-]_L \) by showing the expression of \( [v]_L \) for each \( v \in V \) (Theorem 5). Then we shall employ this characterisation for computing \( \cong_L \).

We will first treat the special case of \( lwa \)'s over a one letter alphabet \( |A| = 1 \). Next we will show how to treat the general case of an arbitrary (finite) alphabet.

We note that for the case of \( |A| = 1 \), the functor \( L \) is isomorphic to \( \mathbb{L} = \mathbb{K} \times A \)

Moreover, the final \( \mathcal{L} \)-coalgebra is isomorphic to the set of streams over the field \( \mathbb{K} \):

\[ \mathbb{K}^* \cong \mathbb{K}^\omega. \]

Therefore we shall proceed by recalling from [35] the basics of stream calculus and linear stream differential equations, in Sections 5.1 and 5.2. Next we shall characterise the final homomorphism, for the case \( |A| = 1 \), in Section 5.3. Building on [33], we shall finally generalise these results for finite alphabets, in Section 5.4.

5.1. Recalling the basics of stream calculus

We define the set of streams over the field \( \mathbb{K} \) by

\[ \mathbb{K}^\omega = \{ \sigma \mid \sigma : \mathbb{N} \to \mathbb{K} \} \]

(\( \mathbb{N} \) is the set of natural numbers).

We often denote elements \( \sigma \in \mathbb{K}^\omega \) by \( \sigma = (\sigma(0), \sigma(1), \sigma(2), \ldots) \). We define the stream derivative of a stream \( \sigma \) by \( \sigma' = (\sigma(1), \sigma(2), \sigma(3), \ldots) \), and the initial value of \( \sigma \) by \( \sigma(0) \). This definition of initial value and derivative of streams forms the basis for a calculus of streams, in close analogy to classical calculus in analysis. Below we present some of its basics; we refer the reader to [34] for further details and motivations.

For \( k \in \mathbb{K} \), we define the constant stream

\[ [k] = (k, 0, 0, 0, \ldots) \]

which we often denote again by \( k \). Another constant stream is

\[ \lambda^i = (0, 1, 0, 0, 0, \ldots). \]

For \( \sigma, \tau \in \mathbb{K}^\omega \) and \( n \in \omega \), the operations of \textit{sum} and \textit{(convolution) product} are given by

\[ (\sigma + \tau)(n) = \sigma(n) + \tau(n), \quad (\sigma \times \tau)(n) = \sum_{i=0}^{n} \sigma(i) \cdot \tau(n-i) \]

(where, as usual \( \cdot \) denotes product of \( \mathbb{K} \)).

We call a stream \( \pi \in \mathbb{K}^\omega \) polynomial if there are \( n \geq 0 \) and \( a_i \in \mathbb{K} \) such that

\[ \pi = a_0 + a_1 \lambda^1 + a_2 \lambda^2 + \cdots + a_n \lambda^n = (a_0, a_1, a_2, \ldots, a_n, 0, 0, 0, \ldots) \]

where we write \( a_i \lambda^i \) for \( [a_i] \times \lambda^i \) with \( \lambda^i \) the \( i \)-fold product of \( \lambda \) with itself. A stream \( \sigma \) with \( \sigma(0) \neq 0 \) has a (unique) multiplicative inverse \( \sigma^{-1} \) in \( \mathbb{K}^\omega \), satisfying

\[ \sigma^{-1} \times \sigma = [1]. \]
As usual, we shall often write $1/\sigma$ for $\sigma^{-1}$ and $\sigma/\tau$ for $\sigma \times \tau^{-1}$. Note that the initial value of the sum, product and inverse of streams is given by the sum, product and inverse of their initial values.

We call a stream $\rho \in K^\omega$ rational if it is the quotient $\rho = \sigma/\tau$ of two polynomial streams $\sigma$ and $\tau$ with $\tau(0) \neq 0$.

One can compute a stream from its initial value and derivative by the so-called fundamental theorem of stream calculus [34]: for all $\sigma \in K^\omega$,

$$\sigma = \sigma(0) + (\lambda' \times \sigma')$$  \hspace{1cm} (4)

(writing $\sigma(0)$ for $[\sigma(0)]$).

The fundamental theorem of stream calculus allows us to solve stream differential equations such as

$$\sigma' = 3 \times \sigma, \quad \sigma(0) = 1$$

by computing $\sigma = \sigma(0) + (\lambda' \times \sigma') = 1 + (\lambda' \times 3 \times \sigma)$, which leads to the solution

$$\sigma = 1/(1 - 3\lambda) = (1, 3, 3^2, 3^3, \ldots).$$

5.2. Solving linear systems of stream differential equations

Using some elementary linear algebra notation (matrices and vectors), we next show how to solve linear systems of stream differential equations. For notational convenience, we shall deal with linear systems of dimension 2, which can be straightforwardly generalised to systems of higher dimensions. They are given by the following data:

$$\left(\begin{array}{c}
\sigma \\
\tau
\end{array}\right) = M \times \left(\begin{array}{c}
\sigma \\
\tau
\end{array}\right), \quad \left(\begin{array}{c}
\sigma \\
\tau
\end{array}\right)(0) = N$$

where $M$ is a $2 \times 2$-matrix and $N$ is a $2 \times 1$-matrix over $K$:

$$M = \left(\begin{array}{cc}
m_{11} & m_{12} \\
m_{21} & m_{22}
\end{array}\right), \quad N = \left(\begin{array}{c}
n_1 \\
n_2
\end{array}\right)$$

for $m_{ij}, n_i \in K$. The above notation is really just a shorthand for the following system of two stream differential equations:

$$\begin{align*}
\sigma' &= (m_{11} \times \sigma) + (m_{12} \times \tau), \quad \sigma(0) = n_1, \\
\tau' &= (m_{21} \times \sigma) + (m_{22} \times \tau), \quad \tau(0) = n_2.
\end{align*}$$

We can solve such a system of equations by using twice the fundamental theorem of stream calculus (Eq. (4) above), once for $\sigma$ and once for $\tau$:

$$\begin{align*}
\sigma &= \sigma(0) + (\lambda' \times \sigma'), \\
\tau &= \tau(0) + (\lambda' \times \tau').
\end{align*}$$

In matrix notation, the fundamental theorem looks like

$$\left(\begin{array}{c}
\sigma \\
\tau
\end{array}\right) = \left(\begin{array}{c}
\sigma \\
\tau
\end{array}\right)(0) + \lambda' \times \left(\begin{array}{c}
\sigma \\
\tau
\end{array}\right).$$

Next we can solve our linear system (5) above by calculating as follows:

$$\begin{align*}
\left(\begin{array}{c}
\sigma \\
\tau
\end{array}\right) &= \left(\begin{array}{c}
\sigma \\
\tau
\end{array}\right)(0) + \lambda' \times \left(\begin{array}{c}
\sigma \\
\tau
\end{array}\right) = N + \lambda' \times M \times \left(\begin{array}{c}
\sigma \\
\tau
\end{array}\right).
\end{align*}$$

This leads to

$$\left(\begin{array}{c}
I - (\lambda' \times M)
\end{array}\right) \left(\begin{array}{c}
\sigma \\
\tau
\end{array}\right) = N$$

where $I$ and $\lambda' \times M$ are given by

$$I = \left(\begin{array}{cc}
1 & 0 \\
0 & 1
\end{array}\right), \quad \lambda' \times M = \left(\begin{array}{cc}
m_{11} \times \lambda' & m_{12} \times \lambda' \\
m_{21} \times \lambda' & m_{22} \times \lambda'
\end{array}\right).$$

Finally, we can express the unique solution of our linear system of stream differential equations as follows:

$$\left(\begin{array}{c}
\sigma \\
\tau
\end{array}\right) = (I - (\lambda' \times M))^{-1} \times N.$$
The advantage of the matrix notations above now becomes clear: we can compute the inverse of the matrix
\[
(I - (\mathcal{X} \times M)) = \begin{pmatrix}
1 - (m_{11} \times \mathcal{X}) & -(m_{12} \times \mathcal{X}) \\
-(m_{21} \times \mathcal{X}) & 1 - (m_{22} \times \mathcal{X})
\end{pmatrix}
\]
whose values are simple polynomial streams, by standard linear algebra.

Let us look at an example. For
\[
M = \begin{pmatrix}
0 & 1 \\
-1 & 2
\end{pmatrix}, \quad N = \begin{pmatrix}
1 \\
2
\end{pmatrix}
\]
our linear system of stream differential equations (5) has the following solution:
\[
\begin{pmatrix}
\sigma \\
\tau
\end{pmatrix} = (I - (\mathcal{X} \times M))^{-1} \times N
\]
\[
= \begin{pmatrix}
1 - \mathcal{X} & -2 \mathcal{X} \\
\mathcal{X} & 1 - \mathcal{X}
\end{pmatrix}^{-1} \times \begin{pmatrix}
1 \\
2
\end{pmatrix}
= \begin{pmatrix}
\frac{1 - 2 \mathcal{X}}{(1 - \mathcal{X})^2} & \frac{\mathcal{X}}{(1 - \mathcal{X})^2} \\
\frac{-\mathcal{X}}{(1 - \mathcal{X})^2} & \frac{1}{(1 - \mathcal{X})^2}
\end{pmatrix} \times \begin{pmatrix}
1 \\
2
\end{pmatrix}
= \begin{pmatrix}
\frac{1 - 2 \mathcal{X}}{(1 - \mathcal{X})^2} \\
\frac{-\mathcal{X}}{(1 - \mathcal{X})^2}
\end{pmatrix} \times \begin{pmatrix}
1 \\
2
\end{pmatrix}.
\]
We note that the solutions of linear systems of stream differential equations always consist of rational streams.

5.3. Characterising the final morphism: |A| = 1

It is easy to see that when |A| = 1, the final coalgebra for the functor \(L\) is \((\mathbb{K}^\omega, ((-)\mathcal{O}, (-)\mathcal{O}'))\) where \((-)\mathcal{O}: \mathbb{K}^\omega \rightarrow \mathbb{K}\) and \((-)\mathcal{O}' : \mathbb{K}^\omega \rightarrow \mathbb{K}^\omega\) map each stream \(\sigma\) to its initial value \(\sigma(0)\) and to its stream derivative \(\sigma'\). Let \((\mathbb{K}^2, (\mathcal{O}, \mathcal{O}'))\) be an lwa, with linear maps \(\mathcal{O} : \mathbb{K}^2 \rightarrow \mathbb{K}\) and \(\mathcal{O}' : \mathbb{K}^2 \rightarrow \mathbb{K}^2\) that are represented by a \(1 \times 2\)-matrix \(O\) and by a \(2 \times 2\)-matrix \(T\). We will now show how the final homomorphism
\[
\begin{array}{ccc}
\mathbb{K}^2 & \xrightarrow{\mathcal{O}} & \mathbb{K}^\omega \\
\downarrow{(\mathcal{O}, \mathcal{O}')} & & \downarrow{(\mathcal{O}(0), \mathcal{O}'(0))} \\
\mathbb{K} \times \mathbb{K}^2 & \xrightarrow{id_{\mathbb{K}} \times \mathcal{O}} & \mathbb{K} \times \mathbb{K}^\omega
\end{array}
\]
can be characterised in terms of rational streams. To this end, we define
\[
\sigma = \left[\begin{array}{c}
\mathcal{O} \\
\mathcal{O}
\end{array}\right]_{\mathbb{K}^2}, \quad \tau = \left[\begin{array}{c}
0 \\
1
\end{array}\right]_{\mathbb{K}^2}.
\]
It follows from the commutativity of the diagram above that
\[
\sigma' = \left[\begin{array}{c}
T(1) \\
0
\end{array}\right]_{\mathbb{K}^2}, \quad \sigma(0) = O\left[\begin{array}{c}
1 \\
0
\end{array}\right],
\]
\[
\tau' = \left[\begin{array}{c}
T(0) \\
1
\end{array}\right]_{\mathbb{K}^2}, \quad \tau(0) = O\left[\begin{array}{c}
0 \\
1
\end{array}\right]
\]
and this can be concisely expressed by the following system:
\[
\begin{pmatrix}
\sigma \\
\tau
\end{pmatrix}' = \mathcal{T} \times \begin{pmatrix}
\sigma \\
\tau
\end{pmatrix}, \quad \begin{pmatrix}
\sigma \\
\tau
\end{pmatrix}(0) = \mathcal{O}
\]
(where the superscript t indicates matrix transpose). These identities present \(\sigma\) and \(\tau\) as the solution of a linear system of stream differential equations. By the results from Section 5.2, it follows that
\[
\begin{pmatrix}
\sigma \\
\tau
\end{pmatrix} = (I - (\mathcal{X} \times \mathcal{O}))^{-1} \times \mathcal{O}
\]
which leads to the following general formula for \([-I]_{\mathbb{K}^2}^L\):

\[
\left[\begin{array}{c}
k_1 \\
k_2
\end{array}\right]_{\mathbb{K}^2}^L = (k_1 \ k_2) \times \left(I - (X \times T^t)\right)^{-1} \times t^t O.
\]

For instance, if 
\[
T = \begin{pmatrix} 0 & -1 \\ 1 & 2 \end{pmatrix}, \quad O = (1 \ 2)
\]

we find, using the example with M and N from Section 5.2, that

\[
\left[\begin{array}{c}
k_1 \\
k_2
\end{array}\right]_{\mathbb{K}^2}^L = \left(k_1 \ k_2 \right) \times \left(I - (X \times M)\right)^{-1} \times N = \left(k_1 + 2k_2 \right) - k_2 \frac{1}{1-X^2}.
\]

Note that the above expression fully characterises \([-I]_{\mathbb{K}^2}^L\), in the sense that it maps each \(v \in \mathbb{K}^2\) in the corresponding rational stream.

**Computing \(\approx_L\).** We can employ the above characterisation in order to compute \(\approx_L\) on \((\mathbb{K}^2, (o,t))\). We use the fact that the final homomorphism identifies precisely all equivalent states:

\[
\left[\begin{array}{c}
x_1 \\
x_2
\end{array}\right] \approx_L \left[\begin{array}{c}
y_1 \\
y_2
\end{array}\right] \iff \left[\begin{array}{c}
x_1 \\
x_2
\end{array}\right]_{\mathbb{K}^2}^L = \left[\begin{array}{c}
y_1 \\
y_2
\end{array}\right]_{\mathbb{K}^2}^L = 0
\]

where the 0 on the right is the stream \([0] = (0, 0, 0, \ldots)\). The kernel of the final homomorphism can now be computed using our characterisation above: for all \(k_1, k_2 \in \mathbb{K}\),

\[
\left[\begin{array}{c}
k_1 \\
k_2
\end{array}\right]_{\mathbb{K}^2}^L = 0 \iff \frac{(k_1 + 2k_2) - k_2 X}{(1-X)^2} = 0 \iff (k_1 + 2k_2) - k_2 X = 0 \iff k_1 = 0 \text{ and } k_2 = 0.
\]

As a consequence, we find, for the present example:

\[
\left[\begin{array}{c}
x_1 \\
x_2
\end{array}\right] \approx_L \left[\begin{array}{c}
y_1 \\
y_2
\end{array}\right] \iff \left[\begin{array}{c}
x_1 \\
x_2
\end{array}\right] = \left[\begin{array}{c}
y_1 \\
y_2
\end{array}\right].
\]

### 5.4. Rational weighted languages

All the results presented above allow to characterise the final homomorphism for weighted automata over an alphabet with a single letter. These results can be generalised in order to deal with alphabets of size greater than one.

Let \(A\) be an arbitrary finite alphabet. Recall from Section 3.3 that the final \(L\)-coalgebra is \((\mathbb{K}^A, (\epsilon, d))\) where for all \(\sigma \in \mathbb{K}^A\) and \(a \in A\),

\[
\epsilon(\sigma) = \sigma(\epsilon), \quad d(\sigma)(a) = \sigma_a
\]

and \(\sigma_a\) denotes the \(a\)-derivatives of the language \(\sigma\).

The calculus presented in the previous section for one-variable power series (streams) can be generalised for multiple variable series [33], which we will recall next.
There are unique operators on series satisfying the following equations. For all $k \in \mathbb{K}$, $a, b \in A$ and $\sigma, \tau \in \mathbb{K}^A^*$,

<table>
<thead>
<tr>
<th>Derivative</th>
<th>Initial value</th>
<th>Name</th>
</tr>
</thead>
<tbody>
<tr>
<td>$k_a = 1,$</td>
<td>$k(\epsilon) = k$</td>
<td>Constant</td>
</tr>
<tr>
<td>$(\lambda_a)_b = 0$</td>
<td>$(\lambda_b)_a = 0$</td>
<td>$a \neq b$</td>
</tr>
<tr>
<td>$(\sigma + \tau)_b = \sigma_a + \tau_b$</td>
<td>$(\sigma(\epsilon) + \tau(\epsilon)) = (\sigma + \tau)(\epsilon)$</td>
<td>Sum</td>
</tr>

</tr>
<tr>
<td>$(\sigma^{-1})_b = -(\sigma(\epsilon)^{-1} \times \sigma_a) \times \sigma^{-1}$</td>
<td>$(\sigma^{-1})(\epsilon) = \sigma(\epsilon)^{-1}, \text{if } \sigma(\epsilon) \neq 0$</td>
<td>Inverse</td>
</tr>
</tbody>
</table>

A weighted language is rational if it can be constructed from finitely many constants $k \in \mathbb{K}$ and variables $\lambda_a$, by means of the operators of sum, product, and inverse. Rational languages constitute the class of languages that are recognised by finite-dimensional weighted automata.

As for streams, one can compute a series from its initial value and derivatives by the so-called fundamental theorem [33]. That is, for all weighted languages $\sigma \in \mathbb{K}^A^*$:

$$\sigma = \sigma(\epsilon) + \sum_{a \in A} \lambda_a^a \times \sigma_a. \quad (6)$$

The fundamental theorem allows us to solve equations, similar to what happened above for streams. As an example, take $A = \{a, b\}$ (weighted languages over two symbols coincide with infinite binary trees), and the following equations

$$\sigma_a = 3 \times \sigma, \quad \sigma_b = 3 \times \sigma, \quad \sigma(\epsilon) = 1.$$

Applying the fundamental theorem we reason as follows:

$$\sigma = \sigma(\epsilon) + (\lambda_a^a \times \sigma_a) + (\lambda_b^b \times \sigma_b)$$

$$\Leftrightarrow \sigma = 1 + (3 \lambda_a^a \times \sigma) + (3 \lambda_b^b \times \sigma)$$

$$\Leftrightarrow (1 - 3 \lambda_a^a - 3 \lambda_b^b)\sigma = 1$$

which leads to the solution $\sigma = (1 - 3 \lambda_a^a - 3 \lambda_b^b)^{-1}$, the tree depicted in the following picture.

![Tree Diagram]

Note that the above language is exactly the one recognised by the automaton in Fig. 1. It is also interesting to remark the strong similarity with streams: the formula for the stream $(1, 3, 9, \ldots)$ is $(1 - 3X)^{-1}$.

Now that we know how to compute the solution of a single equation, moving to systems of equations is precisely as for streams. Again, for notational convenience, we shall exemplify with linear systems of dimension 2. The goal is to solve

$$\begin{pmatrix} \sigma \\ \tau \end{pmatrix}_a = M_a \times \begin{pmatrix} \sigma \\ \tau \end{pmatrix}, \quad \begin{pmatrix} \sigma \\ \tau \end{pmatrix}(\epsilon) = N$$

where, for each $a \in A$, $M_a$ is a $2 \times 2$-matrix and $N$ is a $2 \times 1$-matrix over $\mathbb{K}$.

We now solve this system by calculating as follows (similar to the stream case), now using the fundamental theorem for weighted languages, given in Eq. (6):

$$\begin{pmatrix} \sigma \\ \tau \end{pmatrix} = \begin{pmatrix} \sigma \\ \tau \end{pmatrix}(\epsilon) + \sum_{a \in A} \lambda_a^a \times \begin{pmatrix} \sigma \\ \tau \end{pmatrix}_a$$

$$= N + \sum_{a \in A} \lambda_a^a \times M_a \times \begin{pmatrix} \sigma \\ \tau \end{pmatrix}.$$

This leads to

$$\left( I - \sum_{a \in A} (\lambda_a^a \times M_a) \right) \begin{pmatrix} \sigma \\ \tau \end{pmatrix} = N$$

where $I$ and $\lambda_a^a \times M_a$ are as before.
Finally, we can express the unique solution of our linear system as follows:

\[
\begin{pmatrix}
\sigma \\
\tau
\end{pmatrix} = \left( I - \sum_{a \in A} (X_a \times M_b) \right)^{-1} \times N.
\]

Hence, the only difference with the stream case is that instead of computing the inverse of the matrix \( I - (X \times M) \) one needs to compute the inverse of \( I - \sum_{a \in A} (X_a \times M) \).

Some remarks on computing the inverse of \( I - \sum_{a \in A} (X_a \times M) \) are now in order. Convolution product on power series is not commutative as soon as \( A \) has more than one element (e.g., \( \lambda_a \times \lambda_b \neq \lambda_b \times \lambda_a \)). Thus, the matrix above is a matrix with entries stemming from a non-commutative ring. Traditional methods (Gaussian elimination, Cramer’s rule, quasi-determinants \[14\] or generalised LDU decomposition \[9\]) to compute the inverse of matrices are not applicable and thus one needs to resort to other (more complicated) techniques such as quasi-determinants \[14\] or generalised LDU decomposition \[9\].

A function to compute the inverse of a matrix with non-commutative entries is provided in the Mathematica \[26\] package NCAAlgebra \[30\]. The algorithm implemented in the package is directly base in LDU decomposition \[9\]. The matrices we show below were all obtained using the aforementioned package.

For instance, for \( A = \{ a, b, c \} \), if

\[
M_a = M_c = \begin{pmatrix} 2 & 0 \\ 0 & 0 \end{pmatrix}, \quad M_b = \begin{pmatrix} 0 & 0.5 \\ 0 & 0.5 \end{pmatrix}, \quad N = (1 \quad 1),
\]

then

\[
I - X_a \times M_a - X_b \times M_b - X_c \times M_c = \begin{pmatrix} 1 - 2X_a - 2X_c & -0.5X_b \\ 0 & 1 - 0.5X_b \end{pmatrix}
\]

and

\[
(I - X_a \times M_a - X_b \times M_b - X_c \times M_c)^{-1} = \begin{pmatrix} \frac{1}{1 - 2X_a - 2X_c} & \frac{0.5}{1 - 0.5X_b} \\ \frac{1}{1 - 2X_a - 2X_c} & \frac{1}{1 - 0.5X_b} \end{pmatrix}.
\]

The final homomorphism \([-][]^C_{K^2} \] is represented in the following diagram

\[
\begin{array}{c}
\mathbb{K}^2 \xrightarrow{[-][]^C_{K^2}} \mathbb{K}^A^* \\
\langle o, t \rangle \downarrow \quad \downarrow \langle e, d \rangle \\
\mathbb{K} \times \mathbb{K}^2 \times \mathbb{K} \xrightarrow{id_{\mathbb{K}} \times [-][]^C_{K^2} \times \mathbb{K} \times \mathbb{K}^A^*}
\end{array}
\]

where, as usual, \( o \) and \( t = \{ t_a : \mathbb{K}^2 \rightarrow \mathbb{K}^2 \}_{a \in A} \) are linear mappings represented by the \( 1 \times 2 \)-row vector \( O \) and the \( 2 \times 2 \)-matrices \( T_a \), respectively.

We will show how the final homomorphism \([-][]^C_{K^2} \] can be characterised in terms of rational weighted languages. To this end, we again define

\[
\sigma = \left[ \begin{pmatrix} 1 \\ 0 \end{pmatrix} \right]_{K^2}^C, \quad \tau = \left[ \begin{pmatrix} 0 \\ 1 \end{pmatrix} \right]_{K^2}^C.
\]

It follows from the commutativity of the diagram above that

\[
\sigma_a = \left[ T_a \begin{pmatrix} 1 \\ 0 \end{pmatrix} \right]_{K^2}^C, \quad \sigma (\epsilon) = O \begin{pmatrix} 1 \\ 0 \end{pmatrix},
\]

\[
\tau_a = \left[ T_a \begin{pmatrix} 0 \\ 1 \end{pmatrix} \right]_{K^2}^C, \quad \tau (\epsilon) = O \begin{pmatrix} 0 \\ 1 \end{pmatrix}
\]

and this can be concisely expressed by the following system:

\[
\begin{pmatrix} \sigma \\ \tau \end{pmatrix} = \begin{pmatrix} \sigma_a \\ \tau_a \end{pmatrix} \times \left( \begin{pmatrix} \sigma \\ \tau \end{pmatrix} \right)^{(\epsilon)} = \begin{pmatrix} \sigma \\ \tau \end{pmatrix} (\epsilon) = \begin{pmatrix} \sigma \\ \tau \end{pmatrix} \times \begin{pmatrix} \sigma \\ \tau \end{pmatrix} (\epsilon) = \begin{pmatrix} \sigma \\ \tau \end{pmatrix} = \begin{pmatrix} \sigma \\ \tau \end{pmatrix}
\]

It then follows that

\[
\begin{pmatrix} \sigma \\ \tau \end{pmatrix} = \left( I - \sum_{a \in A} (X_a \times \begin{pmatrix} \sigma \\ \tau \end{pmatrix}) \right)^{-1} \times \begin{pmatrix} \sigma \\ \tau \end{pmatrix}
\]

Finally, we can express the unique solution of our linear system as follows:
which leads to the following general formula for $\mathcal{L}_{K^2}$:

$$\left[\begin{array}{cc} k_1 & k_2 \\ \end{array}\right]_{K^2} = (k_1 \times (1 - \left(\sum_{a \in A} x_a \times \mathbf{1} T_a\right))^{-1} \times \mathbf{1} O.$$

For instance, for $A = \{a, b, c\}$ and

$T_a = T_c = \left(\begin{array}{cc} 2 & 0 \\ 0 & 0 \end{array}\right), \quad T_b = \left(\begin{array}{cc} 0 & 0 \\ 0.5 & 0.5 \end{array}\right), \quad O = (1 \quad 1)$

we find, using the example above, that

$$\left[\begin{array}{cc} k_1 & k_2 \\ \end{array}\right]_{K^2} = (k_1 \times (\sum_{a \in A} x_a \times T_a) \times N^{-1} \times O$$

$$= (k_1 \times (\sum_{a \in A} x_a \times T_a) \times N^{-1} \times O$$

$$= (k_1 \times (\sum_{a \in A} x_a \times T_a) \times N^{-1} \times O$$

$$= \frac{k_1}{1 - 2x_a - 2x_c} + 0.5k_1 \frac{1}{1 - 2x_a - 2x_c} x_b \frac{1}{1 - 0.5x_b} + \frac{k_2}{1 - 0.5x_b}.$$  

By generalising the above arguments from $K^2$ to any finite dimension vector space, we obtain the following theorem.

**Theorem 5.** Let $(V, (o, t))$ be a linear weighted automaton with $V$ finite dimension. Then, for all $v \in V$

$$v = t v \times \left(1 - \left(\sum_{a \in A} x_a \times \mathbf{1} T_a\right)\right)^{-1} \times \mathbf{1} O.$$  

For an example with a three-dimensional state space, we consider the $LWA$ corresponding to the automaton $(V, (o, t))$ in Fig. 5:

$$\left[\begin{array}{cc} k_1 & k_2 & k_3 \\ \end{array}\right]_{V} = (k_1 \times (\sum_{a \in A} x_a \times T_a) \times N^{-1} \times O$$

$$= (k_1 \times (\sum_{a \in A} x_a \times T_a) \times N^{-1} \times O$$

$$= \frac{1}{1 - \lambda_a - \lambda_b} + 0.5 \frac{1}{1 - \lambda_a - \lambda_c} \lambda_b \frac{1}{1 - \lambda_b} + \frac{1}{1 - \lambda_b}.$$  

The inverse of the matrix in the middle is

$$M = \left(\begin{array}{ccc} \frac{1}{1 - \lambda_a - \lambda_b} & 0 & 0 \\ \frac{1}{1 - \lambda_a - \lambda_c} \lambda_b & 1 & \lambda_b \\ \frac{1}{1 - \lambda_a - \lambda_c} \lambda_c & 3 \lambda_b & \frac{1}{1 - \lambda_b} \end{array}\right)$$

and

$$M \times \left(\begin{array}{c} 2 \\ 1 \\ 1 \end{array}\right) = \left(\begin{array}{c} \frac{1}{1 - \lambda_a - \lambda_b} \lambda_c (\lambda_b + 1) \lambda_c \lambda_b \frac{1}{1 - \lambda_a - \lambda_b} + 1 + \lambda_b \frac{1}{1 - \lambda_b} \lambda_b + \frac{1}{1 - \lambda_b} \end{array}\right) = \left(\begin{array}{c} \rho_1 \\ \rho_2 \\ \rho_3 \end{array}\right).$$
Summarising
\[
\begin{bmatrix}
  \frac{k_1}{k_2} \\
  \frac{k_2}{k_3}
\end{bmatrix}_V^C = (k_1 \ k_2 \ k_3) \times \begin{pmatrix}
  \rho_1 \\
  \rho_2 \\
  \rho_3
\end{pmatrix}.
\]

Note that the above expression fully characterises \([-L]_V^C\), in the sense that it maps each \(v \in V\) in the rational weighted language that it accepts.

**Computing \(\approx_L\).** Now, we have a rational expression \(\sigma = k_1 \rho_1 + k_2 \rho_2 + k_3 \rho_3\) characterising the final homomorphism and we would like to calculate for which values of \(k_1, k_2\) and \(k_3\) this expression equals 0. As we have shown before, when \(|A| = 1\), this can be done by syntactically manipulating the rational expression in a standard way. In the general case, because of the non-commutativity of the convolution product, this is not trivial at all.

Here, we choose to adopt the following approach: first we compute "some" derivatives \(\sigma_a, \sigma_b, \sigma_{ab}, \ldots\) and then we check for which \(k_1, k_2\) and \(k_3\) the initial values \(\sigma(\epsilon), \sigma_a(\epsilon), \sigma_b(\epsilon), \sigma_{ab}(\epsilon), \ldots\) are equal to 0. The following lemma (proved in [6,33]) ensures that we have to compute only finitely many derivatives.

**Lemma 5.** **Rational weighted languages have finitely many linearly independent derivatives.**

In our example, we start by taking the initial value of the expression \(\sigma\) itself obtaining \(\sigma(\epsilon) = 2k_1 + k_2 + k_3\). Then we take the \(a\)- and \(b\)-derivatives which give, respectively, the expressions
\[
\sigma_a = k_1(\rho_1)_a + k_2(\rho_2)_a + k_3(\rho_3)_a,
\]
\[
\begin{pmatrix}
  \rho_1 \\
  \rho_2 \\
  \rho_3
\end{pmatrix}_a = \begin{pmatrix}
  2 \\
  \frac{1}{3} \\
  \frac{2}{3}
\end{pmatrix} \times \begin{pmatrix}
  \frac{2}{1-\lambda_a-\lambda_b} \\
  \frac{2}{1-\lambda_a-\lambda_b} \\
  \frac{2}{1-\lambda_a-\lambda_b}
\end{pmatrix}
\]

and
\[
\sigma_b = k_1(\rho_1)_b + k_2(\rho_2)_b + k_3(\rho_3)_b,
\]
\[
\begin{pmatrix}
  \rho_1 \\
  \rho_2 \\
  \rho_3
\end{pmatrix}_b = \begin{pmatrix}
  \frac{1}{3} - \lambda_a - \lambda_b \\
  \frac{2}{1-\lambda_a-\lambda_b} \\
  \frac{2}{1-\lambda_a-\lambda_b}
\end{pmatrix} \times \begin{pmatrix}
  \frac{2}{1-\lambda_a-\lambda_b} \\
  \frac{2}{1-\lambda_a-\lambda_b} \\
  \frac{2}{1-\lambda_a-\lambda_b}
\end{pmatrix}
\]

which have initial values \(\sigma_a(\epsilon) = 2k_1 + \frac{1}{2}k_2 + 2k_3\) and \(\sigma_b(\epsilon) = 2k_1 + \frac{1}{2}k_2 + 3k_3\).

Now, note that the \(a\)-derivative, that is the rational expression (8), will now always generate the same derivatives for \(a\) and \(b\) (since the derivatives of \(\frac{2}{1-\lambda_a-\lambda_b}\) are the expression itself again; intuitively, this expression represents an infinite binary tree with 2's in every node and hence has left and right subtrees equal to the whole tree). For the \(b\)-derivative, we take another level of derivatives and obtain, respectively,
\[
\sigma_{ba} = k_1(\rho_1)_{ba} + k_2(\rho_2)_{ba} + k_3(\rho_3)_{ba},
\]
\[
\begin{pmatrix}
  \rho_1 \\
  \rho_2 \\
  \rho_3
\end{pmatrix}_{ba} = \begin{pmatrix}
  \frac{2}{1-\lambda_a-\lambda_b} \\
  \frac{2}{1-\lambda_a-\lambda_b} \\
  \frac{2}{1-\lambda_a-\lambda_b}
\end{pmatrix} \times \begin{pmatrix}
  \rho_1 \\
  \rho_2 \\
  \rho_3
\end{pmatrix}_a
\]

and
\[
\sigma_{bb} = k_1(\rho_1)_{bb} + k_2(\rho_2)_{bb} + k_3(\rho_3)_{bb},
\]
\[
\begin{pmatrix}
  \rho_1 \\
  \rho_2 \\
  \rho_3
\end{pmatrix}_{bb} = \begin{pmatrix}
  \frac{2}{1-\lambda_a-\lambda_b} \\
  \frac{2}{1-\lambda_a-\lambda_b} \\
  \frac{2}{1-\lambda_a-\lambda_b}
\end{pmatrix} \times \begin{pmatrix}
  \frac{2}{1-\lambda_a-\lambda_b} \\
  \frac{2}{1-\lambda_a-\lambda_b} \\
  \frac{2}{1-\lambda_a-\lambda_b}
\end{pmatrix}
\]
The $a$-derivative coincides with (8) and the $b$-derivative coincides with the original expression $\sigma$. Therefore, we have found the system of equations we need to solve:

$$
\begin{align*}
\sigma(\epsilon) &= 0, \\
\sigma_0(\epsilon) &= 0, \\
\sigma_0(\epsilon) &= 0
\end{align*}
\Leftrightarrow
\begin{align*}
2k_1 + k_2 + k_3 &= 0, \\
2k_1 + \frac{2}{3}k_2 + 2k_3 &= 0, \\
2k_1 + \frac{1}{3}k_2 + 3k_3 &= 0.
\end{align*}
$$

Solving it yields $k_1 = -2k_2$ and $k_2 = 3k_3$. Hence, the kernel of the final homomorphism is the space spanned by the vector

$$
\begin{pmatrix}
-2 \\
3 \\
1
\end{pmatrix}
$$

which coincides with what was computed by the forward algorithm in Section 4.1.

6. Discussion

In this paper we proposed a novel coalgebraic perspective on weighted automata and their behavioural equivalences. Weighted automata are $W$-coalgebras, for a functor $W$ on Set, but they can also be regarded as linear weighted automata, that are $L$-coalgebras for a functor $L$ on Vect. The behavioural equivalence induced by $W$ coincides with weighted bisimilarity, while the equivalence induced by $L (\approx_L)$ with weighted language equivalence.

Weighted languages (i.e. formal power series) form the vector space $K^X$ that carries the final $L$-coalgebra: for each linear weighted automata $(V, (a,t))$, the unique $L$- morphism $[-]_L^v$ into the final co-algebra maps each vector $v \in V$ into the weighted language in $K^X$ that $v$ accepts. The unique morphism $[-]_L^v$ is a linear map and its kernel coincides with $\approx_L$ that, when $V$ is finite dimension, can be computed in three different ways. It is important to remark here that the linearity of $[-]_L^v$ is the key ingredient (in all the three approaches) to finitely compute the equivalence on an infinite state space (represented as a vector space of finite dimension).

Theorem 5 provides an explicit characterisation of $[-]_L^v$ by assigning a syntactic expression denoting a rational weighted language to each vector $v \in V$. This characterisation can be employed for computing $\approx_L$ but, in general terms, it seems to be inconvenient to be implemented in an automatic prover. The backward algorithm, instead, is very efficient but its presentation is a bit complex since it requires dual spaces and transpose maps. The forward algorithm is easier to explain and we have shown it is closely related to the construction of the final co-algebra.

Our coalgebraic perspective has also extended the notions of weighted bisimulation and linear weighted bisimulation (that were introduced in [8] and [7], respectively) to automata having infinite dimension state space. For these automata, bisimilarity and language equivalence are not computable but still these different kinds of bisimulations might be useful as proof techniques.

From fields to semirings. Weighted automata are usually defined on semirings rather than fields [29]. We discuss now that part of the results presented in this paper can be extended to semirings.

Semirings can be thought of as a generalisation of fields, where the product is not necessarily commutative and inverses of sum and product are not required to exist. Semimodules on a semiring generalise the notion of vector spaces on a field. Formally, a semiring $S$ consists of a commutative monoid $(S, +, 0)$ and a monoid $(S, \cdot, 1)$ such that the product distributes over sum (namely, $s_1 \cdot (s_2 + s_3) = (s_1 \cdot s_2) + (s_1 \cdot s_3)$ and $(s_1 + s_2) \cdot s_3 = (s_1 \cdot s_3) + (s_2 \cdot s_3)$) and 0 annihilates with respect to product ($0 \cdot s = s \cdot 0 = 0$). A semimodule on $S$ is a commutative monoid $(V, +, 0)$ equipped with an external action $\cdot: S \times V \rightarrow V$ such that for all $s, s_1, s_2 \in S$ and $v, v_1, v_2 \in V$ (a) $s \cdot (v_1 + v_2) = (s \cdot v_1) + (s \cdot v_2)$, (b) $(s_1 + s_2) \cdot v = (s_1 \cdot v) + (s_2 \cdot v)$ and (c) $(s_1 \cdot s_2) \cdot v = s_1 \cdot (s_2 \cdot v)$. Linear maps between semimodules are defined in the same way as linear maps between vector spaces, namely, as functions preserving $+$ and $(\cdot)$. Semimodules and linear maps form the category $S\text{Mod}$ which has product $(V \times W)$ and exponent $(V^A)$ defined as in Vect. Given a set $X$, a semimodule $V$ and a function $f : X \rightarrow V$, the free semimodule generated by $X$ (denoted by $S^X$) and the linearisation of $f$ (denoted by $f^*$) are defined as for vector spaces.

With these ingredients, we can extend all the results of Sections 2 and 3 (apart from Section 3.4) to semirings. First of all, we would define the semiring valuation functor $S^\omega : \text{Set} \rightarrow \text{Set}$ in the same way as the field valuation functor $K^\omega : \text{Set} \rightarrow \text{Set}$ (Definition 2) and we would model weighted automata using the functor $W = S \times (S^\omega)^A : \text{Set} \rightarrow \text{Set}$. In this way, $W$-coalgebras are in one to one correspondence with weighted automata on $S$ and all the proofs and results of Section 2 are still valid. Then, linear weighted automata (Definition 3) would be defined as coalgebras on $S\text{Mod}$ rather than on Vect. More precisely, coalgebras for the functor $L = S \times -^A : S\text{Mod} \rightarrow S\text{Mod}$. Given an $S$-weighted automata $(X, (o, t))$ we can build the linear weighted automata $(S^\omega, (o^\sharp, t^\sharp))$, where $S^\omega$ is the free semimodule generated by $X$ and $o^\sharp$ and $t^\sharp$ are the linearisations of $o$ and $t$. It is easy to see that all the proofs and results of Section 3.3 are still valid.

The notion of linear relation (Definition 4) relies on the existence of minus operator “-” (the inverse of sum) and thus the results of Section 3.4 cannot be naively extended to generic semirings. The forward algorithm could be extended (by exploiting its relationship with the construction of final coalgebras), but the convergence in a finite number of iterations
might be not guaranteed. The other two procedures strongly rely on the properties of fields and vector spaces (such as the existence of the inverse multiplicative or the dual space). Therefore, it seems challenging to extend them to the case of a generic semiring. If $\mathbb{S}$ is a semifield however, then all elements have a multiplicative inverse and further connections could be explored. An important example of semifield is the tropical semiring $\mathbb{T}$ [19] (for which, however, weighted language equivalence is undecidable [23]). Further, when $\mathbb{S}$ is a commutative ring, annihilators and transpose maps can be generalised as operations carried out within the dual module (i.e., linear maps from an $\mathbb{S}$-module to $\mathbb{S}$, seen as a module) [31]. We leave these extensions as future work.

**Initial weight.** Besides the output weight $o$ and the transition relation $t$, weighted automata are often equipped also with a vector $i$, called initial weight [29]. Initial weights cannot be modelled in our coalgebraic approach and, more generally, coalgebras are usually considered not suitable to model “initial states”. However, instead of the language of a weighted automaton $(X, (t, o, i))$ as in [29] we can equivalently consider the language recognised by vector $i$ of the $\mathcal{L}$-coalgebra $(i^X_o, (i^X_t, i^X_i))$.

Unfortunately, this is possible for $\mathcal{L}$-coalgebras but not for $W$-coalgebras, since the state spaces of the formers are vector spaces, while those of the latters are just sets.

**Related work.** Our approach is closely related to the work presented in [8] whose weighted automata are equipped with initial weights. When restricting the automata in [8] to those having a single initial state (i.e., the initial weight vector contains one 1 and the others are 0s), these closely correspond to $\mathcal{W}$-coalgebras: “forward bisimilarity” of [8] coincides with the coalgebraic $\mathcal{W}$-behavioural equivalence, “functional simulations” are $\mathcal{W}$-homomorphisms and “aggregated automata” for a bisimulation $R$ are the $\mathcal{W}$-coalgebras $(X/R, \langle o_{X/R}, t_{X/R} \rangle)$ of Section 2.

In [8], there are also two notions of “backward bisimulation”, but none of them is related to the equivalences considered in this work. In particular, they are not related to the backward algorithm, since the relations computed by such algorithm are linear and they approximate the complement of language equivalence. Moreover, “backward bisimulation” can be defined in any possible semiring while, as discussed above, the backward algorithm is possible only in some more specific cases.

Computing $\approx_L$ for finite-dimensional linear weighted automata implies the decidability of language equivalence for finite state weighted automata over a field. This was already observed by Schützenberger [38] using a cubic reduction algorithm [6]. By constructing a finite sequence of simulations, decidability of language equivalence for finite state weighted automata over a field is studied in [5]. More recently, this decidability result has been extended to automata with weights over a large class of semiring [12].

In this paper we have shown that an advantage of linear weighted automata is the existence of minimisation algorithms for them. Minimisation algorithms have been extensively studied in the context of deterministic finite state weighted automata [27–29]. While minimisation is not well-defined for automata with weights on a general semiring, a simple and practical algorithm that works for all division semirings, and thus also fields, is given in [11]. When considering only automata with weights over fields, our algorithms are more general, because, they can be used to minimise a non-necessarily deterministic finite state weighted automaton by first determinising it to a linear weighted one.
