Background: External compression is used for pectus carinatum (PC) treatment, but many patients are noncompliant. Costal cartilage resection (CCR) has been described as an alternative, but these approaches sacrifice the internal thoracic arteries (ITA). We aim to assess the feasibility of CCR sparing ITA comparing thoracoscopic and subcutaneous endoscopic approaches.

Methods: Twelve pigs were used as models for surgical PC correction and randomized for 2 groups: thoracoscopy (T) and subcutaneous (subpectoralis) endoscopy (SP). In both groups, CCR from 3rd 4th and 5th ribs was performed avoiding ITA damage. ITA preservation was confirmed by Doppler-ultrasound as well as postmortem injection of methylene blue. Four persons evaluated the procedures being difficult, using a 6-item modified validated scale.

Results: In both techniques, the procedure was accomplished in all animals sparing ITAs. CCR was faster in T than in SP (49 ± 5 vs. 65 ± 16 minutes, p = 0.05). T was classified as easier than SP (p < 0.001) with a significantly higher score for all items, especially better image and tissue handling.

Discussion: Sparing the ITAs during CCR for correction of PC is feasible in a porcine model and might be a goal in humans. The thoracoscopic approach allows for a faster and easier procedure.

Pectus carinatum (PC) is defined as the protrusion of the sternum or the ribs. The overall prevalence is around 0.6% being the second most common chest wall deformity with up to 80% of the cases occurring in male patients [1,2]. Most cases of PC are sporadic, however there seems to be a congenital or hereditary origin, as it can occur as part of a genetic disorder or syndrome (i.e., Ehlers–Danlos syndrome, Marfan syndrome, trisomy 18, homocystinuria or Morquio syndrome) [3]. Hereditary links are suggested by the observation of PC in monozygotic twins, by the neonatal presentation and by increased incidence of other chest wall abnormalities in family members [3]. Although there is no established etiology, an abnormal pattern of cartilage growth and metabolism is thought to be involved in its etiopathogenesis [4,5]. This condition is usually asymptomatic and rarely associated with respiratory symptoms [6]. The unaesthetic appearance of the deformity however, may have psychological impact leading to insecurity, decreased confidence and low self-esteem.

During the last half-century, the standard procedure in the correction of PC was the open approach involving costal cartilage resection, wide pectoralis muscle dissection and sternal osteotomy [7]. The application of pressure over the protruded chest wall using orthosis was a nonsurgical alternative proposed during the nineties, but this alternative is not always successful [6,9]. For these patients, minimally invasive surgical approaches have been proposed, following two main inspiring ideas: the correction of the thoracic malformation by compression of the sternum with a subcutaneous bar [7,10] and the correction by costal cartilage resection [11,12]. Isolated cartilage resection may not be enough to correct bilateral and chondromammary deformities associated with sternal defects. However, multiple costal cartilage resections seem to be a good option for asymmetric unilateral PC avoiding the need for a bar and its subsequent removal reoperation [11,12]. Also in severe asymmetric PC, compressive techniques are not straightforwardly applied, as some patients are noncompliant.

Cartilage resection has been achieved either by thoracoscopic approach [11,12] or by creating an epicostal space, that is, inflating CO2 under the pectoralis major muscle [13]. The number of reported cases is not large and, in the authors’ knowledge, there is no previously published comparison between these two different strategies [11,12].

Kim and Idowu’s [11] and Varela and Torre’s [12] thoracoscopic approaches differ from each other in the extent of cartilage resection; from Varela and Torre’s point of view a more extensive cartilage resection may alter the need for postoperative external compression. However,

a wider resection is not fully harmless; in order to reach the most medial portions of costal cartilages, obliteration of the internal thoracic vessels is required. This could be exceptionable because coronary heart disease is the worldwide leading cause of death and in selected patients coronary artery bypass graft will improve tremendously these patients outcome [14,15,16,17]. Graft patency is associated with long-term survival and left internal thoracic artery (ITA) graft has proved a higher rate of patency at 10 years [18,19,20]. Moreover, in multiple arteries bypass graft, right ITA might be the second best graft as it can further improve long-term survival and reduce adverse events [21].

Given the importance of internal thoracic arteries, this work aims to simulate and assess the feasibility of unilateral pectus carinatum repair with preservation of the internal thoracic vessels by resecting costal cartilages and compare thoracoscopic and subcutaneous (submuscular) endoscopic approaches.

1. Materials and methods

1.1. Design

Twelve pigs (Sus scrofus domesticus) weighing 25 to 35 kg were alternately assigned to a thoracoscopic group (T) and a subpectoralis group (SP), to avoid the effect of a learning curve. In T, 3rd to 5th costal cartilages were resected by thoracoscopy; whereas in SP, the same cartilages were resected by endoscopic approach with subpectoralis approach.

Preservation of the internal thoracic vessels was attempted in both groups. The operative details, acute and postmortem outcomes were assessed and compared. This study was approved by the ethical review board of Minho University (Braga, Portugal).

1.2. Pig preparation

All procedures were performed under general anesthesia with endotracheal intubation and mechanical ventilation. Pigs were submitted to preoperative 8-hour food-fasting or 4-hour water-fasting. The animals were premedicated with a combination of azaperone (4 mg/kg, intramuscular), midazolam (1 mg/kg, intramuscular), and atropine (0.05 mg/kg, intramuscular). Anesthesia was induced with propofol (6 mg/kg, intravenous) and maintained with continuous propofol infusion (20 mg/kg/h, intravenous) and buprenorphine (0.05 mg/kg, intramuscular).

1.3. Surgical technique

In T (Video 1), the pig was placed in lateral decubitus. A 10 mm variable view angle endoscope (EndoCAMeleon® Hopkins®, 26003AE, Karl Storz, Tuttingen, Germany) was introduced through a 11 mm trocar (30123TPS, Karl Storz) located in the fifth intercostal space (ICS) in the posterior axillary line. The capnothorax was established with an inflation rate of 1 L/min and maintained with a pressure up to 6 mm Hg. Two additional 5 mm working ports (30120TRX, Karl Storz) were placed in the forth ICS (anterolaterally) and sixth ICS (anteromedially) as shown in Fig. 1A. Using a 5 mm grasping forceps (CLICKline, 33310ML, Karl Storz) and the hook (Cadiere Monopolar Dissecting L-shaped Electrode, 26775CL, Karl Storz), the lateral insertion of the transverse thoracic muscle was sectioned (Fig. 2). The internal thoracic vessels are then identified, isolated and pushed away from the costal cartilage (medially and posteriorly); special care was taken to coagulate small branches (mediastinal, sternal and perforating branches) to prevent bleeding. With combined use of monopolar hook, endoscopic 45° rongeur (Medtronic Sofamor-Daneck, Memphis, TN, USA) and endoscopic perichondrium elevator (Medtronic Sofamor-Daneck, Memphis, TN, USA) the perichondrium was opened and 3rd, 4th and 5th costal cartilages were almost totally resected, leaving cartilage stumps of less than a centimeter.

In SP (Video 2), the pig was placed in lateral position. A 10 mm incision was made in the posterior axillary line (Fig. 1B) and a working space was created beneath the pectoralis major muscle using forceps. An 11 mm trocar (30123TPS, Karl Storz) was introduced and the CO2 inflated with a pressure up to 18 mm Hg and inflation rate up to 5 L/min. As in T, the same endoscope was introduced and two additional 5 mm working-ports (30120TRX, Karl Storz) were placed under visualization. Further dissection was performed toward the midline and special caution was needed to promptly coagulate any perforating branches of the internal thoracic vessels. The same instruments were used as in T. The pectoralis major, rectus abdominis and serratus anterior muscles were bluntly dissected and eventually cut. The perichondrium was opened and cartilage resected using monopolar hook and the...
endoscopic rangeur. Special care was taken to prevent rupture the posterior perichondrium and ultimately entering the thoracic cavity.

1.4. Main outcome measurements

Perioperative details were recorded, including operative time, feasibility, safety, internal thoracic vessels preservations, injuries and surgical difficulty.

In order to assess the global intraoperative difficulties a modified version of a previous validated index was used: GRITS—Global Rating Index for Technical Skills. This index is not procedure specific and can be applied to a variety of surgeries [22]. Our diagram evaluates the difficulty of the operation with six Likert scale items. The first four are equivalent to the original GRITS table and the last two (instrument conflict, visibility and image quality) were added, replacing incompatible items. As in the original GRITS, each domain is scored from 1 to 5 with anchor descriptors for 1, 3, and 5 scores (Table 1). Two external observers, the surgeon and the assistant evaluated each procedure according to this modified GRITS index. The interrater reliability was measured using the Spearman’s rank correlation coefficient. GRITS scores were compared using Student t test.

At the end of surgery, ITV was checked for patency with regular Doppler ultrasound as in Fig. 3 (Vivid3, General Electric, Connecticut, USA with 12 L probe [4–11 mHz]). The animal was then sacrificed with an overdose of pentobarbital (100–150 mg/kg) following the guidelines of animal experimentation [23] and ITV integrity and patency was confirmed by the methylene blue test. This test consisted in the injection of both vessels (artery and vein) with methylene blue; the vessels were considered “preserved” when the abdominal wall acquired a blue coloration (Fig. 4) and no perivascular leaks were noticed.

2. Results

The procedure was safely completed and preservation of the ITA was accomplished in all animals from both groups. ITA patency and flux were confirmed by Doppler-ultrasound (Fig. 3) and the methylene blue test in every case (Fig. 4). The operative data are presented in Table 2. The surgical procedure was significantly quicker in the T group (49 ± 5 versus 65 ± 16 minutes, p < 0.05). In the T group, two cases presented with lung adhesions; these were initially divided using monopolar hook and the surgery proceeded with no additional difficulties. In the remaining pigs there were no complications or relevant difficulties.

In the SP group, there was the need for muscle section in order to reach the costal cartilage. The serratus anterior and the rectus abdominis have costal and sternal insertions that ultimately required to be divided. In one animal, the pleural cavity was opened during this process. The pleural opening induced an iatrogenic capnothorax and did not permit to maintain high CO₂ inflation pressures. Even with lower inflation pressures, our team struggled to sustain adequate ventilation and this was the cause of frequent time-consuming stops. Nevertheless, resection was accomplished in this case (Table 2). At the end of the surgery, there was significant subcutaneous thoracoabdominal emphysema in all SP pigs, as shown in Fig. 5.

Regarding the reliability of the modified GRITS, there was a significant interrater reliability with an average level of agreement (ρ) of

of ITV preservation and patency has also been raised in the correction of pectus excavatum using the Nuss procedure, in which there seems to be the frequent collapse of ITV. However, there are no clear data regarding the patency after the removal of the bar [26,27].

Pediatric thoracic surgeons should bear in mind that coronary heart disease is the worldwide leading cause of death and coronary artery bypass graft may improve the outcome [18,19,20,21,29,30]. Saphenous vein grafts have a patency rate of 60% at 10 years, while patency rates for left internal thoracic artery (ITA) at 10 years are as high as 98% [18,19,20]. Graft patency is associated with a long-term survival and an attempt is made to place at least one arterial graft. Combined use of multiple arterial grafts (two or more) has a better long-term survival and the second best graft after the left ITA is the right ITA [18,19,20,21,29,30]. It might be questionable to correct a deformity with such a strong male predominance, in detriment of the potentially therapeutic value of both internal thoracic arteries in coronary artery disease. Our work has proven that sparing the ITV during cartilage resection for correction of unilateral PC is feasible in a porcine model. In the thoracoscopic approach, even though we performed wide cartilage resections, ITV preservation was feasible by dissecting, coagulating small branches and pulling away the vessels.

There are two described options for the cartilage resection: by dissecting under the pectoralis major muscle and in

Fig. 4. Methylene blue test: after injection of the dye and no leakage (arrow). Note the highlighted perfusion territories of the ITA (blue coloration of the muscles and skin).

3. Discussion and conclusions

Chest wall protrusions are classified in two main forms: chondromedullary or chondrogladiolar pectus carinatum. Additionally, it can be described as symmetrical or asymmetrical, according to the bilateral or unilateral position of the protrusion [3]. Often this condition is totally asymptomatic but there may be associated symptoms. As the reported physiologic studies in PC patients are sparse, the association of PC and respiratory dysfunction is controversial. Nevertheless, PC may result in psychological difficulties and limitations. Usually these are intraventricular patients refraining from social activities in which their chest could be exposed, developing insecurity and reducing confidence and self-esteem. As the functional impact of the surgery is doubtful, most authors’ main indication is based on cosmesis, purpose to improve quality of life [6,24,25].

The best treatment of PC deformities is still debated and investigated. The classic operation is an aggressive open surgery; as there were no minimally invasive solutions and there are no clear surgical indications, PC was named the “untreated chest deformity” [6,7]. In the last decades, compression of the protruded thoracic deformity using an orthosis was a breakthrough. However it requires long-term adhesion and the lack of immediate effects potentially leads to noncompliance [8,9].

For asymmetric unilateral PC multiple costal cartilage resections have been reported with no bar use or its subsequent removal reoperation [11,12,13]. In the previously reported techniques it was not always possible to preserve the internal thoracic vessels (ITV). The issue of ITV preservation and patency has also been raised in the correction of pectus excavatum using the Nuss procedure, in which there seems to be the frequent collapse of ITV. However, there are no clear data regarding the patency after the removal of the bar [26,27].

Pediatric thoracic surgeons should bear in mind that coronary heart disease is the worldwide leading cause of death and coronary artery bypass graft may improve the outcome [18,15,16,17,28]. Saphenous vein grafts have a patency rate of 60% at 10 years, while patency rates for left internal thoracic artery (ITA) at 10 years are as high as 98% [18,19,20]. Graft patency is associated with a long-term survival and an attempt is made to place at least one arterial graft. Combined use of multiple arterial grafts (two or more) has a better long-term survival and the second best graft after the left ITA is the right ITA [18,19,20,21,29,30]. It might be questionable to correct a deformity with such a strong male predominance, in detriment of the potentially therapeutic value of both internal thoracic arteries in coronary artery disease. Our work has proven that sparing the ITV during cartilage resection for correction of unilateral PC is feasible in a porcine model. In the thoracoscopic approach, even though we performed wide cartilage resections, ITV preservation was feasible by dissecting, coagulating small branches and pulling away the vessels.

There are two described options for the cartilage resection: by dissecting under the pectoralis major muscle and inflating the neo-cavity with CO2 and by thoracoscopic approach [11,12,13]. There were no previous studies comparing the two approaches and few cases have been reported [11,12,13]. Based on our findings, the thoracoscopic approach (T) was quicker and seems to be a more “muscle sparing” technique; in SP there was the inevitable need to cut muscle fibers in order to reach the cartilages, as the muscles are actually inserted over the cartilage. There is also the risk to perforate into the chest cavity, which occurred in one case and made the surgery more difficult, but not impossible, or life threatening. The authors were also concerned about the substantial subcutaneous emphysema extending caudally to the pelvic region observed in all SP cases. One possibility is that too high

Please cite this article as: Lamas-Pinheiro R, et al, Sparing internal thoracic vessels in thoracoscopic or submuscular correction of pectus carinatum: A porcine model study, J Pediatr Surg (2015), http://dx.doi.org/10.1016/j.jpedsurg.2015.07.023
CO₂ pressures were used (18 mm Hg versus 15 mm Hg reported by Schaarschmidt [13,31]) and this issue might be addressed only by lowering the pressure, otherwise the SP could be associated with significant morbidity. There are no reported data regarding this possible complication, and the only stated concern was a moderate rise in systemic CO₂ [13,31]. Although more than three costal cartilages can be resected by thoracoscopic, sternal osteotomy might be difficult and risky, whereas in previous studies, it was possible to perform more aggressive surgical techniques using the subpectoralis approach, including sternal osteotomies to repair sternal deformities [13,31].

The two approaches were also compared regarding their difficulty, using a modified version of the previously validated GRITS. The new index proved to be very consistent despite any modification, as there was a significant inter-rater reliability with an average level of agreement (ρ) of 0.328 (near all possible pairs had a two-tailed p value lower than 0.05). The GRITS data show that thoracoscopic is the easiest approach: there was less instrument conflict and more appropriate handling of the tissues, resulting in more efficiency and less awkward movements with a better flow of the operation. Additionally, there was better image quality with better visualization of the working field by optimized view angles (Table 3). The authors believe that the major muscle sections in SP, represented a worst tissue handling, were time-consuming and ultimately impaired the image quality because of the smoke being released during the frequent cautery use.

Using a porcine model it was possible to recreate and simulate the same surgical steps required for costal cartilage resection, but the authors recognize the limitation of a nonsurvival animal study. It was not possible to access the outcomes based on esthetic results or improvements in quality of live, and those are probably the main goals of the procedure [25]. Therefore it may be difficult to extrapolate which approach will have better outcomes in the real world, however the preservation of the ITV should be a milestone.

In conclusion, this work shows that there is no need to sacrifice the ITA to resect costal cartilages and hopes to make surgeons aware of this issue. Thoracoscopic approach is efficient, faster and easier, offers a better image quality and requires less muscle damage than subcutaneous approach.
