Abstract
Amorphous α,ω-hidroxylpoly(ε-caprolactone) (PCL(530))/siloxane ormolytes doped with manganese perchlorate (Mn(ClO$_4$)$_2$) (d-PCL(530)/siloxane$_n$Mn(ClO$_4$)$_2$) with n = 20, 50, and 100), thermally stable up to at least 200 °C, were synthesized by the sol-gel method. Ionic conductivity values up to $4.8 \times 10^{-8}$ and $2.0 \times 10^{-6}$ S cm$^{-1}$ at about 25 and 100 °C, respectively, were obtained for n = 20. FT-IR data demonstrated that the hydrogen bonding interactions present in the non-doped d-PCL(530)/siloxane host hybrid matrix were significantly influenced by the inclusion of Mn(ClO$_4$)$_2$ which promoted the formation of more oxyethylene/urethane and urethane/urethane aggregates. In addition, the Mn$^{2+}$ ions bonded to all the “free” C=O groups of the urethane cross-links and to some of the “free” ester groups of the amorphous PCL(530) chains. In the electrolytes, the ClO$_4^-$ ions were found “free” and bonded to the Mn$^{2+}$ ions along a bidentate configuration. The magnitude of the electron paramagnetic resonance (EPR) hyperfine constant of the analyzed samples ($A \approx 90 \times 10^{-4}$ cm$^{-1}$) suggested that the bonding between Mn$^{2+}$ ions and the surrounding ligands is moderately ionic. The synthetized d-PCL(530)/siloxane$_n$Mn(ClO$_4$)$_2$ biohybrids have potential application in paramagnetic, photoelectrochemical and electrochromic devices.

Keywords: poly(e-caprolactone)/siloxane biohybrids, manganese perchlorate, sol-gel, ionic conductivity, paramagnetism.
1. Introduction

Polymer electrolytes (PEs) have attracted much interest to the scientific community because of their technological application in the domain of solid state electrochemistry, in particular for the fabrication of advanced batteries, sensors, photoelectrochemical, and electrochromic devices (ECDs) [1-3]. Actual research on solid-state electrochemistry seeks a compromise between “green” technologies, low cost, and highly efficient materials.

In the framework of the investigation of new “green” materials with improved properties and potential application as electrolytes in ECDs, several ormolyte (organically modified silicate electrolyte) systems composed of a sol-gel derived [4] poly(ε-caprolactone) (PCL(530), where 530 represents the average molecular weight in g mol\(^{-1}\))-based di-urethanesil hybrid network (abbreviated as d-PCL(530)/siloxane) (Fig. 1) have been tested in the last few years. Doping of this organic-inorganic hybrid matrix with lithium [5-8], potassium [9], magnesium [10], europium [8], and erbium [6] salts, europium complexes [11] and ionic liquids [5] resulted in materials with attractive features, in particular high ionic conductivity and in the case of the lanthanide-containing systems also high luminescence, and foreseen applications in eco-friendly ECDs. Prior to these works, applications of PCL and PCL-based hybrids had been proposed almost exclusively for the biomedical field, as biodegradable suture, artificial skin, resorbable prostheses, containers for sustained drug delivery, or bioactive coatings [12-20]. In fact PCL is a linear biopolymer that possesses interesting features, such as biocompatibility, permeability, hydrophobicity, biodegradability, non-toxicity for living organisms, and the ability of being resorbed after a certain period of implantation time.

In the present work, the d-PCL(530)/siloxane biohybrid was doped with manganese perchlorate (Mn(ClO\(_4\))\(_2\)). The incorporation of Mn\(^{2+}\) ions has a two-fold interest,
endowing the resulting hybrids with ionic conductivity and specially paramagnetic properties.

Indeed Mn$^{2+}$ is a transition metal ion that has been extensively used as paramagnetic probe and as activator in various luminescent materials [21, 22]. Mn$^{2+}$-doped phosphors can be effectively excited by many sources, such as ultraviolet (UV), X-ray, and electric field [23-26] to yield emissions in the green, orange and red regions of the visible spectrum [21, 27, 28]. These emission properties motivated the wide use of Mn$^{2+}$-based materials as phosphors for lamps and displays [25, 27, 29, 30]. Recently, Wang et al. [31] proposed the use of carbon-coated manganese silicate to act as anode material for lithium storage, exhibiting outstanding rate performances and high-rate cycling stability, and meeting the requirement for fast charging/discharging Li$^+$ batteries.

In this study, the structure, morphology, thermal features, ionic conductivity, and paramagnetic properties of the Mn(ClO$_4$)$_2$-doped d-PCL(530)/siloxane biohybrids are reported. The elucidation of the paramagnetic features has been performed by means of electron paramagnetic resonance spectroscopy (EPR), which is an effective and highly sensitive technique for the characterization of local order in a variety of solid–state systems [32-34]. EPR can provide valuable information about the oxidation state, ground state, and spin state of the paramagnetic ion. It enables the determination of the local symmetry of the ion environment, the nature of relevant spin interactions (e.g., Zeeman interaction, fine structure splitting, hyperfine coupling and exchange interaction) and the extent of covalency of the metal-ligand bond. EPR studies using Mn$^{2+}$ ion as a probe have been very useful in the understanding of both the local coordination symmetry and magnetic properties of Mn$^{2+}$ ions incorporated in a variety of materials, such as glasses [35-37], zeolites [38-40] and polymers [41].
We believe that the present investigation represents an important contribution towards the understanding of the interactions between the d-PCL(530)/siloxane systems and metal ions.

2. Experimental

2.1 Materials

Manganese (II) perchlorate (Mn(ClO$_4$)$_2$·xH$_2$O, 99%, Aldrich) was dried under vacuum at room temperature for several days prior to being used. α,ω-hydroxypoly(ε-caprolactone) (PCL (530), MW = 530 g mol$^{-1}$, Fluka) and 3-isocyanatepropyltriethoxysilane (ICPTES, 95%, Aldrich) were used as received. Ethanol (CH$_3$CH$_2$OH, 99.9%, Merck) and tetrahydrofuran (THF, 99.9%, Merck) were stored over molecular sieves. High-purity deionized water (H$_2$O) was used in all experiments.

2.2 Synthesis

The Mn(ClO$_4$)$_2$-doped d-PCL(530)/siloxane-based biohybrids were prepared based on the procedure described in detail elsewhere [7]. The first stage of the synthesis involved the formation of a urethane cross-link between the hydroxyl (-OH) end groups of the PCL(530) (0.8 g, 1.5 mmol) chains and the isocyanate (-N=C=O) groups of ICPTES (745 µL, 3.0 mmol) to yield the organic-inorganic hybrid precursor. This reaction occurred in THF medium at 70-80 ºC and in a sealed flask. The grafting process was infrared monitored during the formation of the urethane groups. The intensity of the strong and sharp band, characteristic of the stretching vibration of the -N=C=O group of ICPTES and typically located at 2273 cm$^{-1}$ was progressively reduced until it
disappeared upon completion of the reaction. In parallel, a series of new bands, associated with the vibrations of the urethane group, appeared in the 1800–1500 cm$^{-1}$ spectral region. The d-PCL(530)/siloxane precursor was obtained as a yellowish transparent oil.

In the second stage of the synthesis procedure, a mixture of CH$_3$CH$_2$OH (705 µL, 12.1 mmol) and H$_2$O (82 µL, 4.6 mmol) was added to the d-PCL(530)/siloxane precursor obtained in the previous step to promote the hydrolysis and condensation reactions characteristic of the sol-gel process. The molar ratio ICPTES:CH$_3$CH$_2$OH:H$_2$O used was 1:4:1.5. An appropriate mass of Mn(ClO$_4$)$_2$ (Table 1) was incorporated immediately after the addition of CH$_3$CH$_2$OH and H$_2$O. The final mixture was stirred for 30 min and then cast into a Teflon mould, which was covered with Parafilm and left in a fume cupboard for 24 h. Xerogel films were produced after aging for 1 month in an oven at 50 ºC followed by drying under vacuum at 90 ºC for 3 days prior to being analyzed.

The biohybrids prepared were produced as yellowish flexible xerogel films (Fig. 2) and were identified using the notation d-PCL(530)/siloxane$_n$Mn(ClO$_4$)$_2$, where $n$ (salt composition) indicates the number of (-C(=O)(CH$_2$)$_5$O-) PCL repeat units per Mn$^{2+}$ ion. Samples with $n = 100$, 50 and 20 were prepared (Table 1).

2.3 Characterization
The total ionic conductivity of the samples was determined by locating an electrolyte disk between two 10 mm diameter ion-blocking gold electrodes (Goodfellow, >99.95%) to form a symmetrical cell. The electrode/ormolyte/electrode assembly was secured in a suitable constant volume support and installed in a Büchi TO51 tube oven with a K-type thermocouple (precision of about ± 0.2 °C) placed close to the electrolyte disk to measure the sample temperature. Bulk conductivities of the electrolyte samples were obtained during heating cycles using the complex plane impedance technique with the Autolab PGSTAT-12 (Eco Chemie) equipment between room temperature (± 20 °C) and 100 °C and at approximately 10 °C intervals. The ionic conductivity was evaluated for frequencies between 500 mHz and 65 kHz.

Differential scanning calorimetry (DSC) measurements were performed in a Mettler Toledo DSC 821e calorimeter. Prior to the analyses, the samples were dried in a desiccator containing phosphorous pentoxide (P₂O₅) for 3 days. The DSC analyses were conducted over a temperature range of 0 to 300 °C, at a heating rate of 10 °C min⁻¹, and under argon purge with 50 mL min⁻¹ rate flow. All films were sealed in standard 40 µL aluminum crucibles (Mettler Toledo).

Thermogravimetric analysis (TGA) were performed with a Shimadzu TGA-50 equipment. The measurements were conducted between 30 and 900 °C, at a heating rate of 10 °C min⁻¹, and under a nitrogen atmosphere with 60 mL min⁻¹ rate flow. Before each analysis and aiming to eliminate the traces of solvent and/or absorbed water, all the samples were subject to a first run from 30 to 105 °C, at a heating rate of 20 °C min⁻¹, followed by a second isothermal run at 105 °C during 10 minutes.

Polarized optical microscopy (POM) images were recorded using an OPTIKA B-600POL microscope equipped with a 8 Mpixel digital Photo Camera. The images were analyzed using the OPTIKA Vision Pro software.
X-ray diffraction (XRD) measurements were carried out at room temperature with X-ray Rigaku Utma 4 diffractometer, power of 50 kV/50 mA and Cu Kα irradiation, speed of 2 °C min⁻¹, in an angle range (2θ) of 3 to 60°, at room temperature.

Attenuated total reflectance Fourier transform infrared (ATR/FT-IR) spectra were registered in a Thermo Scientific Nicolet iS50 FTIR spectrometer, coupled to an ATR accessory with a diamond crystal. The instrument is controlled by the Omnic software package (version 9.2.28) from Thermo Fisher Scientific Inc. The spectra were collected in the 4000-400 cm⁻¹ range by averaging 64 scans at a resolution of 4 cm⁻¹. To deconvolute complex band envelopes, the non-linear curve-fitting procedure offered by the PeakFit software [42] was employed. To automatically place hidden peaks, the Residuals procedure was used. This procedure initially places peaks by finding local maxima in a smoothed data stream. Hidden peaks are then optionally added where peaks in the residuals occur. The best fit of the experimental data was obtained using Gaussian shapes and by varying the frequency, bandwidth, and intensity of the bands. A linear baseline correction with a tolerance of 0.2 % was employed. The standard errors of the curve-fitting procedure were < 0.03.

X-band continuous-wave electron paramagnetic resonance (CW-EPR) spectra were recorded at 50 K on a Bruker Elexsys E580 spectrometer operating at 9.478 GHz, equipped with a continuous flow liquid helium Oxford cryogenic system. Solid state powder EPR spectra were simulated by the function “pepper” of the software package EasySpin [43] implemented in MATLAB (MathWorks, Inc.).

3. Results and Discussion

3.1 Thermal characterization
The DSC thermograms of the d-PCL(530)/siloxane\textsubscript{20}Mn(ClO\textsubscript{4})\textsubscript{2} biohybrids (Fig. 3) confirm the entirely amorphous character of the doped samples indicating that the addition of the salt did not alter the disordered nature of the host hybrid matrix [7]. In the case of d-PCL(530)/siloxane\textsubscript{20}Mn(ClO\textsubscript{4})\textsubscript{2} and d-PCL(530)/siloxane\textsubscript{50}Mn(ClO\textsubscript{4})\textsubscript{2} a week broad endothermic peak is seen at ca. 98 °C (onset at about 36 °C) and at ca. 91 °C (onset at about 14 °C), respectively. This endotherm probably corresponds to the loss of adsorbed solvent(s).

The DSC curve of the salt (Fig. 3) displays two endothermic peaks centred at ca. 50 °C ($T_{\text{onset}}$ at ca. 46 °C) and 155 °C ($T_{\text{onset}}$ at ca. 145 °C). While the former event corresponds to a phase transition, a phenomenon often encountered in perchlorate salts [44, 45], the latter endotherm is associated with Mn(ClO\textsubscript{4})\textsubscript{2} melting [46]. None of these two peaks is seen in the DSC curves of the doped d-PCL(530)/siloxane materials suggesting the complete dissociation of Mn(ClO\textsubscript{4})\textsubscript{2} in the d-PCL(530)/siloxane medium.

The thermal behavior of the d-PCL(530)/siloxane\textsubscript{n}Mn(ClO\textsubscript{4})\textsubscript{2} biohybrids was also evaluated by TGA. The TGA curves shown in Fig. 4 demonstrate that below 200 °C all the xerogel samples are thermally stable. The onset of thermal degradation of the d-PCL(530)/siloxane\textsubscript{n}Mn(ClO\textsubscript{4})\textsubscript{2} materials is lower than that reported for the non-doped d-PCL(530)/siloxane network (around 300 °C) [9] indicating that the presence of this guest salt had a non-stabilizing influence on the host d-PCL(530)/siloxane framework under an inert atmosphere. However, this value is similar to that found earlier for d-PCL(530)/siloxane-based ormolytes doped with a mixture of LiCF\textsubscript{3}SO\textsubscript{3} and Er(CF\textsubscript{3}SO\textsubscript{3})\textsubscript{3} [6]. Between 200 and 300 °C all the samples suffered an abrupt weight loss. At 300 °C the d-PCL(530)/siloxane\textsubscript{20}Mn(ClO\textsubscript{4})\textsubscript{2} hybrid revealed a dramatic weight loss of about 25 %. Interestingly, this marked weight loss of this salt-rich sample is similar to that observed in the case of the Mn(ClO\textsubscript{4})\textsubscript{2} TGA curve. In the 300-500 °C temperature range the thermal decomposition of all the doped samples was a multistep
process (Fig. S1). Between 500 and 900 °C, a plateau was attained and no further thermal degradation occurred. At the maximum temperature analyzed about 20 % of the xerogels with n = 100, 50 and 20 still remained to be decomposed. In summary, the progressive incorporation of Mn(ClO₄)₂ into d-PCL(530)/siloxane had a gradual negative impact on the thermal stability of the host framework. However, the thermal decomposition onset value is considered adequate for solid-state electrochemical devices.

3.2 XRD and POM analyses
The XRD patterns of d-PCL(530)/siloxaneₙMn(ClO₄)₂ biohybrids display a broad peak, Gaussian in shape and centered at ca. 21° (Fig. 5a). This peak, which is associated with ordering of the siliceous domains [47] reveals that the incorporation of the manganese salt did not affect the amorphous character of the non-doped d-PCL(530)/siloxane matrix [7, 9]. The POM images of the biohybrids (Fig. 5b) demonstrate the isotropic character of the samples, corroborating the XRD and DSC.

3.3 Ionic conductivity
Ac Impedance spectroscopy was employed to evaluate the electrochemical properties of the biohybrids. The results are presented through Nyquist plots (imaginary impedance Z’’ versus real impedance Z’) (Fig. 6) and a plot of the temperature dependence of the ionic conductivity (Fig. 7).

The ionic conductivity was measured during the heating cycles and determined by Eq. 1,

\[ \sigma = \frac{d}{A \times R_b} \] (1)
where $d$ is the thickness, $A$ is the electrochemical active area and $R_b$ is the bulk resistance obtained from the intercept of the imaginary impedance (minimum value of $Z''$) with the slanted line in the real impedance ($Z'$) through the Randles circuit [48]. The Nyquist plots of Fig. 6 illustrate the mobility of ions due to charge transfer and diffusion processes. Typically, the Nyquist plot is described by three distinct parts: a semicircle located at the high-frequency range that corresponds to the charge transfer process, a straight line for lower frequencies that is related to the diffusion process, and the transition between these phenomena [2, 3]. In the three cases reproduced in Fig. 6 the semi-circle at higher frequencies indicates that the salt facilitates the charge transfer process due to the increase of ionic conductivity with respect to the non-doped matrix [10]. The decrease of the semi-circles diameter also suggests that the ion diffusion ability is improved with salt content. Accordingly, the analysis of Fig. 7 allows inferring that the progressive addition of salt to d-PCL(530)/siloxane induced the enhancement of the ionic conductivity. The highest values were measured at $n = 20$ (4.8×10$^{-8}$ and 2.0×10$^{-6}$ S cm$^{-1}$ at about 25 and 100 ºC, respectively).

The temperature dependence of the ionic conductivity of the hybrid samples, displayed in Fig. 7, appears to follows the vehicular model, i.e., Vogel-Tamman-Fulcher (VTF) type profile in the measured temperature range. As the temperature increases, the polymer segments has acquired sufficient energy to push against the hydrostatic pressure imposed by its neighboring ions and thus polymer can expand easily to produce free volume. The free volume around the polymer chains determines the resulting conductivity, represented by the overall mobility of ions and the polymer. Therefore, as temperature increases, ions or polymer segments can move into the free volume [49]. The ionic conductivity values exhibited by the ormolytes prepared in this work indicate that they are suitable for application on photoelectrochemical and electrochromic devices [50, 51]. The levels of ionic
conductivity are also of the same order of magnitude as those reported for analogous hybrids doped with potassium [9] and magnesium [10] triflates, and approximately one order of magnitude lower than those measured for analogues doped with lithium [7-10, 52, 53] or copper [7-10, 52, 53] salts.

3.4 FT-IR analysis

In the d-PCL(530)/siloxane hybrid medium the Mn$^{2+}$ ions may coordinate to the available functional groups provided by the host hybrid framework (the ether –C=O–C–oxygen atoms and the ester C=O oxygen atoms of the PCL chains, and the urethane C=O oxygen atoms of the cross-links) or naturally to the counter-ions (i.e., the perchlorate ions) [54]. Given the minor amount of ether groups per PCL repeat unit, it is clear that the C=O oxygen atoms will essentially the main responsible for Mn$^{2+}$ coordination. Therefore, upon incorporation into the host hybrid, these cations will bind to “free” urethane/ester C=O groups or to C=O groups present in hydrogen-bonded aggregates. In the latter case, the Mn$^{2+}$ ions need to destroy hydrogen bonds of these aggregates, leading to their partial or complete destruction. To evaluate the influence of Mn$^{2+}$ doping on the strength and extent of the hydrogen bonding interactions in the d-PCL(530)/siloxane matrix, we carried out an FT-IR spectroscopic analysis of the samples in the 1800-1600 cm$^{-1}$ spectral interval, usually known as the amide I band. This band can be resolved into several individual components corresponding to different C=O environments: from “free” C=O groups (in the high-frequency range) to hydrogen-bonded aggregates of variable strength (in the mid-to-low-frequency range).
The FT-IR spectrum of the non-doped d-PCL(530)/siloxane matrix exhibits four components situated at 1762, 1736, 1720, and 1692 cm\(^{-1}\) [11]. Each of these bands is associated with different C=O chemical environments: the 1762 cm\(^{-1}\) and 1736 cm\(^{-1}\) bands are attributed to “free” C=O groups of the urethane cross-links (A1) and of the ester groups of amorphous PCL(530) chains (A2), respectively; the 1720 cm\(^{-1}\) band indicates the presence of oxyethylene/urethane hydrogen-bonded aggregates (B1); whereas the components around 1692 and 1670 cm\(^{-1}\) are assigned to the absorption of C=O groups belonging to significantly more ordered hydrogen-bonded urethane/urethane (C1) and ester/urethane (C2) aggregates [11, 55-57], respectively.

Fig. 8a shows the FT-IR spectra in the “amide I” region of d-PCL(530)/siloxane\(_n\)Mn(ClO\(_4\))\(_2\) biohybrids. Although no significant differences are seen in the global spectral profile for \(n = 100, 50, \) or 20, the inclusion of Mn(ClO\(_4\))\(_2\) into d-PCL(530)/siloxane led to changes in the environment of the C=O groups which are revealed in the “amide I” region in terms of band reorganization. The incorporation of increasing quantities of the guest salt (\(n = 100, 50\) and 20) into the d-PCL(530)/siloxane host resulted in the complete saturation of the “free” C=O groups from the urethane cross-links (A1) and in a considerable reduction of the amount of “free” ester groups of the amorphous PCL(530) chains (A2) (Fig. 8b). In parallel the fraction of oxyethylene/urethane and urethane/urethane hydrogen-bonded aggregates (B1 and C1, respectively) increased significantly. The concentration of ester/urethane aggregates (C2) did not suffer, however, major changes over the whole salt concentration range studied.

The inspection of the spectral signature of the ClO\(_4^-\) ion in the FT-IR spectra of the d-PCL(530)/siloxane\(_n\)Mn(ClO\(_4\))\(_2\) biohybrids allowed us gaining further insight into the local environment of the Mn\(^{2+}\) ions. This was made possible because the ClO\(_4^-\) ion is one of the most extensively employed ions probes in spectroscopic analyses aiming at
elucidating ionic association [58]. As this ion has vibration modes that suffer characteristic changes (e.g., frequency shifts, splitting and/or intensity variations) upon coordination, it allows distinguishing the three main types of ionic species usually present in salt/polymer electrolytes: (a) high mobility “free” or weakly bonded ions; (b) low-mobility cations bonded strongly to the host polymer; (c) low-moderate mobility ionic aggregates (contact ion pairs and ionic multiplets).

The “free” ClO$_4^-$ ion (tetrahedral symmetry (T$_d$)) has nine vibrational degrees of freedom distributed between four normal Raman active modes: $\nu_1$ (A1) (infrared inactive), $\nu_2$ (E2) (infrared inactive), $\nu_3$ (T2), and $\nu_4$ (T2). These modes are expected at 931, 458, 1100 and 624 cm$^{-1}$, respectively [59, 60]. Cation coordination lowers the ClO$_4^-$ ion local symmetry leading to band splitting of degenerate vibrations and to activation of infrared-forbidden modes. The strength of ion association is manifested in the magnitude of band separation and of the frequency shift. Mono- or tridentate coordination of the oxygen atoms of ClO$_4^-$ to a cation lowers the T$_d$ symmetry to C$_{3v}$. As a consequence, the 3-fold degenerate $\nu_3$ and $\nu_4$ vibrations split into two components (A1 and E), both in the infrared and Raman spectra. Bidentate coordination of the oxygen atoms of ClO$_4^-$ to a cation lowers the T$_d$ symmetry to C$_{2v}$. The splitting of the 2-fold degenerate $\nu_2$ vibration into two bands (A1 and A2) in the Raman spectrum and the splitting of the 3-fold degenerate $\nu_3$ and $\nu_4$ vibrations into three components (A1, B1, and B2) in the infrared and Raman spectra result.

In the present work we examined the $\nu_4$ClO$_4$ region of the FT-IR spectra of the d-PCL(530)/siloxane$_n$Mn(ClO$_4$)$_2$ biohybrids samples (Fig. 9(a)). The results of the curve-fitting performed (Fig. 9(b) and Table 2) reveal that in the three samples studied the ClO$_4^-$ ions were either “free” or bonded to the Mn$^{2+}$ ions along a bidentate configuration. The marked growth of the integral area fraction of the 632 cm$^{-1}$ component (Fig. 9(c)) resulting from the incorporation of increasing amounts of
Mn(ClO$_4$)$_2$ to the host hybrid matrix indicates that the proportion of bidentate ClO$_4^-$ ions increased. A major reduction in the fraction of “free” ions occurred concomitantly, as demonstrated by the dramatic decrease of the integral area fraction of the 625 cm$^{-1}$ component.

Table 2. Composition dependence of the integral area fraction (%) of the resolved components (cm$^{-1}$) of the d-PCL(530)/siloxane$_n$Mn(ClO$_4$)$_2$ biohybrids in the FT-IR $\nu_3$ClO$_4$ region.

3.5. Electron Paramagnetic Resonance (EPR)

Fig. 10 shows the X-band CW-EPR spectrum measured at 50 K of the d-PCL(530)/siloxane$_n$Mn(ClO$_4$)$_2$ biohybrids with increasing salt concentration of. In all the EPR spectra the signal consisted of a sextet with effective $g$-value $g \approx 2.0$ (centered at around 3300 G). The Mn$^{2+}$ ion has a 3$d^5$ electronic configuration, a spin $S = 5/2$, and
ground state $^6S_{5/2}$. The lowest orbital level of the free ion is a singlet, which is six-fold degenerate in spin. An axial or tetragonal distortion of the octahedral crystal field splits this singlet into three Kramer’s doublets: $\pm 5/2$, $\pm 3/2$, and $\pm 1/2$ [32, 33]. The application of a magnetic field lifts the spin degeneracy of the Kramers’ doublets, and as a consequence the resonances observed in the EPR spectra are due to transitions within the Kramers’s doublets. The resonance at $g \approx 2.0$ is associated with Mn$^{2+}$ ions in an environment close to octahedral symmetry and is believed to arise from transition within the $\pm 1/2$ Kramer doublet [61-64].

Mn has a stable isotope with non-zero nuclear spin ($^{55}$Mn) with $I = 5/2$ (100 % natural abundance). The EPR spectra of the Mn$^{2+}$ ions at low Mn$^{2+}$ concentration is further split into six lines by the hyperfine structure resulting from the dipole-dipole interaction between the magnetic moment of the $^{55}$Mn nuclei and the electronic moment of the paramagnetic Mn$^{2+}$ ion. The resonance at $g \approx 2.0$ is due to allowed $M_s = \frac{1}{2} \leftrightarrow -\frac{1}{2}$ magnetic dipolar transitions (selection rules $\Delta M_s = \pm 1$ and $\Delta m_1 = 0$, where $M_s$ and $m_1$ are the electronic and nuclear spin state, respectively) from the $^6S_{5/2}$ ground state of Mn$^{2+}$.

The spectra of Fig. 10 are similar to those reported for disordered materials, such as glasses and polymers. The weak features between the spin-allowed hyperfine lines of the resonance signal were attributed to spin "forbidden" transitions ($\Delta M_s = \pm 1$, $\Delta m_1 = \pm 1$) [65-67].

The EPR spectrum of the Mn$^{2+}$ ions in the d-PCL(530)/siloxane host can be qualitatively understood in terms of the spin-Hamiltonian for $d^5$ ions in axial symmetry [68]:

$$H = g\beta H \cdot S + D\left[S^2 - \frac{1}{3}S(S+1)\right] + AS \cdot I$$  \hspace{1cm} (2)
where $\beta$ is the Bohr magneton, $H$ is the applied magnetic field, $S$ is the spin component along the symmetry axis $z$, $A$ is the hyperfine coupling constant, and the other symbols have their usual meaning. The first term in the Hamiltonian represents the interaction of the $S = 5/2$ electron spin with the external magnetic field $H$, i.e., the electron Zeeman interaction. For simplicity, the isotropic $g$-value was considered. The second term is the zero-field splitting (ZFS) Hamiltonian and is characterized by the axial crystal field parameter $D$. The third term is the hyperfine interaction describing the interaction between the $S = 5/2$ electron spin with the $I = 5/2$ nuclear spin of the $^{55}$Mn isotope.

The experimental Mn$^{2+}$ EPR spectra were analyzed by numerical simulation of the spin Hamiltonian (Eq. 2). Satisfactory fits to the experimental EPR spectra were obtained assuming two different Mn$^{2+}$ species characterized by different coordination symmetries. The fit parameters for the species I included the $g$-value, $A$, and $D$. A strain parameter (specified by $D$-strain) was also introduced to account for the heterogeneity of the environments around the paramagnetic center, which results in broad distributions of the principal values of the $D$-tensor \[43\]. The Hamiltonian parameter $D = 612 – 661$ MHz ($204 – 220 \times 10^{-4}$ cm$^{-1}$) deduced from the simulated spectra (Table 3) suggests that the Mn$^{2+}$ ions of species I are complexed by the d-PCL(530)/siloxane matrix in an axially distorted coordination symmetry. The fit parameters for the species II included only $g$ and $A$ (i.e., $D = 0$ MHz). A strain parameter (noted as $A$ strain) was used in samples with lower Mn$^{2+}$ concentration ($n = 50$ and 100) to account for the distribution of $A$ values. For simplicity, $S = 1/2$ for the simulations of species II was assumed. The Hamiltonian parameters obtained for species II suggests that these Mn$^{2+}$ ions are not coordinated to the matrix. The simulated spectra, shown in Fig. 10, were obtained by adding the contribution from species I and II with the Hamiltonian parameters given in Table 3. The agreement between the observed and the calculated spectra are
satisfactory, since the simulated spectra closely reproduce the position and the intensities of the most prominent features.

Table 3. Summary of the spin Hamiltonian parameters of d-PCL(530)/siloxane
Mn(ClO₄)₂ biohybrids obtained from the simulation of the experimental EPR spectra measured at 50 K. Lwpp refers to the peak-to-peak line width for isotropic broadening used for convolution of the CW-EPR spectrum. The first and second elements are the Gaussian and Lorentzian contributions, respectively. It should be noted that the $A$ and $D$ values are given in MHz units usually used in EPR simulation packages (conversion factor is 1 [cm$^{-1}$] = 0.33356×10$^{-4}$ [MHz]).

The value of the hyperfine constant has been correlated with the nature of the bonding character between the Mn$^{2+}$ ions and its ligands in the hybrid electrolytes. The correlation, which is mainly determined by the electronegativity of the Mn$^{2+}$ neighbors, was ascertained by Van Wieringen [69, 70]. In covalent semiconductors like Mn–Te, $A$ values are as low as 59×10$^{-4}$ cm$^{-1}$, while in fluorite crystals, where the bonding is ionic, $A ≈ 97×10^{-4}$ cm$^{-1}$ [35, 71]. The magnitude of the hyperfine constant derived for the
samples in the present work \((A \approx 90 \times 10^{-4} \text{ cm}^{-1}, \text{Table 2})\), suggests that the bonding between Mn\(^{2+}\) ions and the surrounding ligands is moderately ionic. This result is consistent with our previously reported study in Cu\(^{2+}\)-doped d-PCL(530)/siloxane-based electrolytes, where the molecular bonding coefficients \(\alpha^2\) and \(\beta^2\) obtained by correlating the Cu\(^{2+}\) EPR spin Hamiltonian parameters and the optical absorption data suggested that bonding between the Cu\(^{2+}\) and its ligands was also moderately ionic [53]. These conclusions are in perfect agreement with the FT-IR data reported in the previous section in which solid spectral evidences were found pointing out strong interaction between the Mn\(^{2+}\) ions and the C=O groups of the urethane cross-links and of the ester groups of the PCL(530) chains and also between the Mn\(^{2+}\) ions and the ClO\(_4^-\) ions. These two different cation environments could correspond to species I and II identified by EPR, respectively.

4. Conclusions

Paramagnetic amorphous d-PCL(530)/siloxane-based biohybrids doped with Mn(ClO\(_4\))\(_2\) were synthesized by sol-gel method. The incorporation of Mn\(^{2+}\) ions had a two-fold interest, endowing the resulting hybrids with ionic conductivity and paramagnetic properties. The ionic conductivity increased with salt concentration. The highest values were obtained for \(n = 20\) \((4.8 \times 10^{-8} \text{ and } 2.0 \times 10^{-6} \text{ S cm}^{-1} \text{ at about } 25 \text{ and } 100 \text{ }^\circ\text{C}, \text{respectively})\).

The hydrogen bonding interactions present in the d-PCL(530)/siloxane matrix were influenced by the inclusion of Mn(ClO\(_4\))\(_2\), which promoted the formation of more oxyethylene/urethane and urethane/urethane aggregates. In the samples the Mn\(^{2+}\) ions interact with the “free” urethane and ester C=O groups of the host hybrid matrix host
and also with the ClO$_4^-$ ions along a bidentate configuration. “Free” ClO$_4^-$ ions were also detected, although their concentration decreased, as expected, with salt content. The magnitude of the EPR hyperfine constant of the analyzed samples ($A = 90 \times 10^{-4}$ cm$^{-1}$) is in agreement with the FT-IR data suggesting that the bonding between Mn$^{2+}$ ions and the surrounding ligands is moderately ionic. The Mn$^{2+}$ ions identified as species I are coordinated to the d-PCL(530)/siloxane matrix along an axially distorted coordination symmetry, whereas the Mn$^{2+}$ bounded to ClO$_4^-$ ions are classed as species II.

The ionic conducting, combined with the thermal stability up to at least 200 °C and the paramagnetic properties, open interesting prospects for the potential application of the d-PCL(530)/siloxane$_n$Mn(ClO$_4$)$_2$ biohybrids in paramagnetic, photoelectrochemical and electrochromic devices.
