Abstract: A multistart (MS) clustering technique to compute multiple roots of a system of nonlinear equations through the global optimization of an appropriate merit function is presented. The search procedure that is invoked to converge to a root, starting from a randomly generated point inside the search space, is a new variant of the harmony search (HS) metaheuristic. The HS draws its inspiration from an artistic process, the improvisation process of musicians seeking a wonderful harmony. The new hybrid HS algorithm is based on an improvisation operator that mimics the best harmony and uses the idea of a differential variation, borrowed from the differential evolution algorithm. Computational experiments involving a benchmark set of small and large dimensional problems with multiple roots are presented. The results show that the proposed hybrid HS-based MS algorithm is effective in locating multiple roots and competitive when compared with other metaheuristics.

Keywords: nonlinear equations, multistart, harmony search, differential evolution

1 Introduction

Some problems in engineering, chemistry, physics, medicine and economics aim at determining the roots of a system of equations. In general, these problems are nonlinear and difficult to solve. The most popular technique to solve nonlinear equations is the Newton’s method [1]. It is a computationally expensive method since the Jacobian matrix and the solution of a system of linear equations are required at each iteration. On the other hand, Quasi-Newton methods are less expensive since they avoid either the necessity of computing derivatives, or the need of solving a full linear system per iteration or both tasks [2,3,4]. However, they assume that the functions are smooth so that derivatives can be properly approximated by finite differences. Another disadvantage of the traditional Newton-type methods is that their convergence and practical performance are highly sensitive to the provided initial approximations. In most practical cases, it is not an easy task to guess a good initial approximation. Furthermore, they are only capable of finding one root at each run of the algorithm.

This study extends the work presented in [5,6]. Here, we aim at investigating the performance of a multistart (MS) method combined with the harmony search (HS) metaheuristic to compute multiple roots of a system of nonlinear equations of the form

\[ f(x) = 0, \]

where \( f(x) = (f_1(x), f_2(x), \ldots, f_n(x))^T \), each \( f_i : \Omega \subset \mathbb{R}^n \rightarrow \mathbb{R}, i = 1,\ldots,n \) is a continuous possibly nonlinear function in the search space and \( \Omega \) is a closed convex set, herein defined as \([l,u] = \{ x : -\infty < l_i \leq x_i \leq u_i < \infty, i = 1,\ldots,n \}\}. We do not assume that the functions \( f_i(x), i = 1,\ldots,n \) are differentiable. Thus, we are interested in deriving a derivative-free technique that does not assume smoothness, convexity and differentiability. The problem of solving a nonlinear system of equations can be naturally formulated as a global optimization problem. Problem (1) is equivalent to

\[ \min_{x \in \Omega \subset \mathbb{R}^n} \mathcal{M}(x) \equiv \sum_{i=1}^{n} f_i(x)^2, \]

in the sense that they have the same solutions. These required solutions are the global minima, and not just the local minima, of the function \( h(x) \), known as merit function, in the set \( \Omega \). Problem (2) is similar to the usual least squares problem for which many iterative methods have been proposed. They basically assume that the objective function is twice continuously differentiable. However, the objective \( h \) in (2) is only once differentiable if some, or just one, of the \( f_i \), \( i = 1, \ldots, n \) are not differentiable. Thus, methods for solving the least squares problem cannot be directly applied to solve (2).

Preventing premature convergence to a local while trying to locate global solutions of problem (2) is the goal of the present study. Here, we are concerned with the performance of a metaheuristic to solve global optimization problems without the use of derivative information. Metaheuristics are general heuristic methods which can be applied to a wide variety of optimization problems. In the last decade, algorithms based on metaheuristics have been proposed to solve systems of nonlinear equations mainly using the reformulation (2) [7, 8, 9, 10, 11, 12, 13]. In general, they do not require any information concerning root location, since they are able to converge to the solutions starting from points that can be randomly generated in the search space. Furthermore, their performance do not depend on any type of derivative information.

Although finding a single root of a system of nonlinear equations is a trivial task, finding all roots is one of the most demanding problems. Approaches that combine metaheuristics with techniques that modify the objective function in problem (2) have been reported in the literature [8, 10]. The technique in [8, 12] relies on the assignment of a penalty term to each previously computed root so that a repulsion area around the root is created. In [10], an evolutionary optimization algorithm is used together with a type of polarization technique to create a repulsion area around previously computed roots. A multobjective evolutionary approach is another technique available for locating multiple roots [14, 15]. MS methods are very popular and simple stochastic techniques that emerge when multiple solutions to problems are required [16, 17, 18, 19]. When an MS strategy is implemented, a search procedure is applied to a set of randomly generated points of the search space aiming to converge to the multiple solutions of the problem in a single run. However, the same solutions may be computed more than once. Convergence to previously computed solutions can be avoided by implementing a clustering technique which aims to define prohibited regions based on the closeness to the previously computed solutions [13, 17]. Each time a point is randomly selected from these prohibited regions, it will be discarded since the implementation of the search procedure will eventually produce one of the previously computed solutions. Most MS approaches implement a local search algorithm rather than a global one, when trying to locate a solution. The basic idea is to search for a highly accurate solution in a specified and small region, starting from a randomly selected promising point. Good local search procedures, like the traditional BFGS Quasi-Newton method, have been used in the past. The well-known ‘MinFinder’ and the ‘Ideal Multistart’ are two examples of this kind of multistart paradigms [13, 17, 19]. Unfortunately they use first derivatives of the involved functions to define the most promising direction to search for the required solution. However, in the present study we aim to find multiple solutions as efficient as possible without relying on analytic or numerical derivatives. Thus, a search procedure has to be implemented that is capable of finding high quality solutions targeting reduced computational requirements. The basic HS algorithm that emerged in 2001 relies on a set of points and is inspired by natural phenomena [20]. It draws its inspiration not from a biological or physical process like most metaheuristic optimization techniques, but from an artistic one – the improvisation process of musicians seeking a wonderful harmony. HS has efficient strategies for exploring the entire search space, as well as techniques to exploit locally a promising region to yield a high quality solution in a reasonable time. The dynamic updating of two important parameters in the HS algorithm has improved the efficiency and robustness of the metaheuristic [21].

In this study, we borrow the ideas present in the global best variant of HS [22], propose self-adaptive updating rules for two relevant parameters in HS, and hybridize the HS algorithm with a mutation strategy quite common in the differential evolution (DE) method introduced in [23]. The herein proposed HS algorithm will be denoted by hybrid HS algorithm. Previous studies related with the HS and DE algorithms confirm that these metaheuristics are effective in computing one single root of system (1) [5, 6]. However, the present work extends some of the previous ideas to the problem that consists of locating multiple roots of nonlinear systems like (1). This issue is herein addressed by using an MS strategy that relies on an attraction radius to prevent convergence to previously computed solutions, so reducing the overall required computational effort.

This paper is concerned with computing multiple roots of a system of nonlinear equations using an MS paradigm and the HS algorithm hybridized with a DE mutation as an effective search procedure. Thus, Section 2 reports on the hybrid HS algorithm and Section 3 addresses the MS strategy. Then, some numerical experiments are shown in Section 4 and we conclude the paper in Section 5.

### 2 Hybrid HS algorithm

First, the main ideas behind the basic HS algorithm [20] and two other popular versions of the algorithm available in the literature [21, 22] are presented. Second, an introduction to the DE algorithm [23] is included. Finally, the hybrid version of the HS algorithm, combining the HS
paradigm with the DE mutation operator, aiming to increase the exploration feature of the HS algorithm, is described.

2.1 The HS algorithm

The HS algorithm was developed to solve global optimization problems in an analogy with the music improvisation process where music players improvise the pitches of their instruments to obtain better harmony [20, 24]. An overview of the existing variants of the HS is presented by Ali and Mandava in [25]. At each iteration $k$, the basic HS algorithm provides a set of solution vectors from which the best and the worst solutions, in terms of their fitness - objective function values - are selected. Table 1 lists the most relevant nomenclature used in the basic HS algorithm.

The HM is a memory with HMS solution vectors that are maintained in memory throughout the iterative process. The HMCR and PAR parameters are used to find globally and locally improved solutions, respectively. After generating the HM randomly in the search space $\Omega$, $x^1, j = 1, \ldots, HMS$, the vectors are evaluated and the best harmony, $x^{best}$, and the worst, $x^{worst}$, in terms of objective/merit function value are selected. Thereafter, a new harmony is improvised meaning that a new vector $y$ is generated using three improvisation operators:

$O_1$: HM operator;
$O_2$: random selection operator;
$O_3$: pitch adjustment operator.

The HMCR parameter varies between 0 and 1 and gives the probability of choosing the component of the new harmony/vector from the HM (operator $O_1$). Otherwise, the component is randomly generated in $\Omega$ (operator $O_2$):

$$y_i = \begin{cases} x^j_i, & \text{if } rand() < \text{HMCR} \\ l_i + \text{rand}() (u_i - l_i), & \text{otherwise} \end{cases}$$

for $i = 1, \ldots, n$, where $\text{rand}()$ represents a random number in the range $(0, 1)$. The operator $O_3$ is subsequently applied with probability PAR to refine only the components $i$ produced by $O_1$, as follows:

$$y_i = \begin{cases} y_i + \text{rand}() \cdot BW, & \text{if } \text{rand}() < \text{PAR} \\ y_i, & \text{otherwise} \end{cases}$$

(4)

where $BW$ is an arbitrary distance bandwidth. Finally, the HM is updated. The new harmony is compared with the worst harmony in the HM, in terms of $M$ values. The new harmony is included in the HM, replacing the worst one if it is better than the worst harmony. Algorithm 1 presents the main steps of the basic HS algorithm. As shown in (4), the classical HS algorithm uses fixed value for both PAR and BW. However, small values of PAR with large values of BW can considerably increase the number of iterations required to converge to an optimal solution of (2). Experience has shown that BW must take large values at the beginning of the iterative process to enforce the algorithm to increase the diversity of solution vectors. However, small BW values in the final iterations increase the fine-tuning of solution vectors. Furthermore, large values of PAR combined with small values of BW usually cause the improvement of best solutions in the final stage of the process. To eliminate the drawbacks due to fixed values of PAR and BW, an improved HS (I-HS) algorithm is proposed in [21]. The I-HS uses parameter values dynamically dependent on the iteration number $k$, as shown:

$$\text{PAR}(k) = \frac{\text{PAR}_{\text{min}} + k \cdot (\text{PAR}_{\text{max}} - \text{PAR}_{\text{min}})}{NI}$$

(5)

where $\text{PAR}_{\text{min}}$ and $\text{PAR}_{\text{max}}$ are the minimum and maximum pitch adjusting rate respectively, and

$$\text{BW}(k) = \text{BW}_{\text{min}} e^c, \text{ for } c = \frac{\ln(\frac{\text{BW}_{\text{min}}}{\text{BW}_{\text{max}}})}{NI}$$

(6)

where $\text{BW}_{\text{min}}$ and $\text{BW}_{\text{max}}$ are the minimum and maximum bandwidth respectively.

In [22], a new variant of HS, called the global-best harmony search (gb-HS), is proposed. The pitch-adjustment step of the HS is modified in a way that
the new harmony can mimic the best harmony in the HM, adding a social dimension to the HS and replacing the BW related parameters altogether. Thus, the new pitch adjustment operator, \( O_3 \), is applied with probability \( \text{PAR}(k) \), computed from (5), to refine only the components produced by \( O_1 \), in the following way:

\[
y_i = \begin{cases} 
  x_i^{\text{best}}, & \text{if } \text{rand}(\cdot) < \text{PAR}(k) \\
  y_i, & \text{otherwise}
\end{cases} 
\]

where \( \text{best} \) is the index of the best harmony in the HM.

### 2.2 The DE algorithm

Algorithm 2 contains the pseudocode of the basic DE algorithm [23]. This is an evolutionary population-based technique that relies on three operators – mutation, crossover and selection – to define the \( m \) points for the next iteration. The most commonly used mutation is referred to as \( \text{DE/rand/1} \) and defines the mutant point, \( v^j \), as follows:

\[
v^j = x^i + F(x^i - x^j) \quad (8)
\]

with uniformly chosen random indices \( r_1, r_2, r_3 \) from the set \( \{1, 2, \ldots, m\} \), mutually different and \( F \) is a real parameter in \([0, 2]\) which controls the amplification of the differential variation, \( x^{r_2} - x^{r_3} \). The indices \( r_1, r_2 \) and \( r_3 \) are also chosen to be different from the index \( j \). \( x^j \) is called the base point. There are other frequently used mutation strategies, for instance, the \( \text{DE/best/1} \), which uses the best point of the population as the base point:

\[
v^j = x^\text{best} + F(x^i - x^j) \quad (9)
\]

where \( x^\text{best} \) is the best point in the current population. The crossover operator aims to increase the diversity on the components of the mutant point. Thus, the crossover point, called trial point, \( y^j \), is formed as:

\[
y_i^j = \begin{cases} 
  v_i^j, & \text{if } \text{rand}(\cdot) \leq CR \text{ or } i = s_j \\
  x_i, & \text{otherwise}
\end{cases} 
\]

for \( i = 1, \ldots, n \), where \( \text{rand}(\cdot) \) denotes a random number in \((0, 1)\) and aims to perform the mixing of the component \( i \) of the points, \( CR \in [0, 1] \) is the parameter for crossover, and the index \( s_j \), randomly selected from \( \{1, \ldots, n\} \), ensures that \( y^j \) gets at least one component from \( v^j \).

### 2.3 The hybrid HS algorithm

To develop a new hybrid HS algorithm, the ideas from the gb-HS algorithm to/improve a new harmony and the \( \text{mutation} \) operator present in DE to increase the explorative power of the classical HS are used. The new proposal replaces the improvisation operator \( O_1 \) by another one that mimics the best harmony and uses the \( \text{mutation} \) operator of the DE algorithm [23]. Basically, the idea is to generate a trial point by adding the weighted difference between two points to a third one [5]. Thus, the parameter \( \text{HMCR} \) sets the probability of choosing the component of the new harmony from the best harmony in HM adding a differential variation, i.e., for each \( i = 1, \ldots, n \):

\[
y_i = \begin{cases} 
  x_i^\text{best} + F(x_i^j - x_i^{r_1}), & \text{if } \text{rand}(\cdot) < \text{HMCR} \\
  x_i^j, & \text{if } \text{rand}(\cdot) \geq \text{HMCR}
\end{cases} 
\]

\[
y_i = \begin{cases} 
  l_i + \text{rand}(\cdot)(u_i - l_i), & \text{if } \text{rand}(\cdot) < \text{HMCR} \\
  x_i^j, & \text{otherwise}
\end{cases} 
\]

(11)

is used instead of (3), where \( F \in [0, 2] \) and the indices \( j_1, j_2 \) are randomly chosen values from the set \( \{1, \ldots, \text{HMS}\} \). However, when these indices are different, a randomly chosen component of a point randomly selected from the HM is selected, to diversify the search.

We note that when defining \( y \), some components can be generated outside the domain \( \Omega \). Thus, each component should be checked and a projection to the bounds is carried out:

\[
y_i = \begin{cases} 
  l_i, & \text{if } u_i - l_i \leq 0 \\
  u_i, & \text{otherwise}
\end{cases} 
\]

(12)

In the HS context, to further explore the search space for a promising region where a global solution lies, the pitch adjustment operator \( (O_3) \) is maintained although the parameters \( \text{PAR} \) and \( \text{BW} \) are updated according to new self-adaptive rules. The proposed updating rule for the probability \( \text{PAR} \) ensures that the larger values appear in the final iterations and are combined with small values of the bandwidth \( \text{BW} \) (as shown below in (13)):

\[
\text{PAR} = \frac{1}{1 + \alpha f(x^{\text{worst}})}
\]

where \( x^{\text{worst}} \) is the worst harmony in the HM in terms of the merit function (at the current iteration). For the BW, an
adaptive value for each component \( i = 1, \ldots, n \) is assigned as follows

\[
BW^i = BW^i_{\text{max}} \left( 1 - \frac{1}{1 + e^{\left( x^{\text{worst}}_i \right)}} \right),
\]

where \( BW^i_{\text{max}} = u_i - l_i \) depends on the lower and upper bounds of each component \( i \).

3 Multistart algorithm

MS methods are mainly used to locate multiple solutions of bound constrained optimization problems [16,17,18,19,26], although they can be used to locate multiple solutions of other kind of problems [8,10,13]. MS repeatedly invokes a search procedure starting from a set of randomly generated points of the search space aiming to converge to the multiple solutions of the problem. However, the same solutions may be computed over and over again. To avoid convergence to previously computed solutions, a clustering technique that defines prohibited regions based on the closeness to the previously located solutions may be integrated into the multistart algorithm. This way, points that are generated from these prohibited regions are discarded since the search procedure would converge most certainly to a previously located solution.

Hence, to compute multiple roots of a set of nonlinear equations like the one in (1), computing global minimizers of the problem (2), the herein implemented MS methodology uses a clustering technique to avoid convergence to an already located solution. The exploration feature of the MS strategy is carried out by generating points randomly spread all over the search space \( \Omega \). The exploitation of promising regions is carried out by invoking a search procedure starting from each of the randomly generated points. In contrast to the line search BFGS method presented in [19], our proposal for the search procedure relies on a global search heuristic that is capable of computing global minimizers of a merit function with high quality and reduced computational effort.

The presented clustering technique also uses the concept of regions of attraction of previously identified solutions. First, the region of attraction of a minimizer \( \chi_i \), associated with a search procedure, herein denoted by \( \text{HS} \), is defined as:

\[
A_i \equiv \{ x \in [l, u] : \text{HS}(x, \mathcal{R}, [l, u]) = \chi_i \} ,
\]

where \( \chi_i \) is the global, eventually a local (non-global), minimizer produced by the hybrid HS algorithm which is applied in the search space \([l, u]\), starting with \( x \in \mathcal{R} \) and randomly generating the remaining HMS-1 points of the HM inside the region \( \mathcal{R} \). The ultimate goal of the MS algorithm is to invoke the procedure \( \text{HS} \) as many times, say \( N \) times, as the number of global solutions of (2). If a generated point \( x \in [l, u] \) belongs to a region of attraction \( A_i \) then the solution \( \chi_i \) would be obtained when the hybrid HS algorithm starts with a HM which includes the point \( x \). The idea is to apply the hybrid HS algorithm only when \( x \) does not belong to any of the regions of attraction of already computed solutions, or equivalently to the union of those regions of attraction, since they do not overlap. The probability \( p \) that a randomly generated point will not belong to the union of the regions of attraction of \( r \) already computed solutions, can be estimated by

\[
p = \text{Prob}[ x \notin \bigcup_{i=1}^{r} A_i ] = \prod_{i=1}^{r} \text{Prob}[ x \notin A_i ] \approx \text{Prob}[ x \notin A_o ]
\]

where \( A_o \) is the region of attraction of the nearest to \( x \) solution \( \chi_o \) (see details in [19]). The region of attraction \( A_o \) of a solution \( \chi_o \) could be estimated by an exhaustive enumeration of all starting points that converge to \( \chi_o \). Alternatively, an \textit{a priori} estimation involves the probability \( \text{Prob}[ x \notin B(\chi_o, R_o)] \) where \( B(\chi, R) \) denotes the hyper-sphere (henceforth denoted by sphere) centered at \( \chi \) with a radius \( R \).

Let the maximum attractive radius of the minimizer \( \chi_i \) be defined by:

\[
R_i = \max \left\{ \| x^{(j)} \| - \chi_i \right\} ,
\]

where \( x^{(j)} \) is one of the generated points that made the hybrid HS algorithm to converge to \( \chi_i \). Given \( x \), let \( d_i = \| x - \chi_i \| \) be the distance of \( x \) to \( \chi_i \). We remark that:

1. if \( d_i \geq R_i \) then \( x \) is likely to be outside the region of attraction of \( \chi_i \);

2. on the other hand, if \( d_i < R_i \), and the direction from \( x \) to \( \chi_i \) is descent then \( x \) is likely to be inside the region of attraction of \( \chi_i \); however, if the direction from \( x \) to \( \chi_i \) is ascent then \( x \) is likely to be outside the region of attraction of \( \chi_i \).

In case 1., the hybrid HS search procedure could be invoked, with \( x \) as one of the points in the HM, since a new solution could be obtained with high probability. However, when the direction from \( x \) to \( \chi_i \) is descent, there is a high probability that the search procedure will converge to the previous \( \chi_i \), thus the hybrid HS procedure might not be invoked. Thus, the probability that \( x \notin A_i \) is estimated by:

\[
\text{Prob}(x \notin A_i) \approx \begin{cases} 1, & \text{if } d_i \geq R_i \\
\phi, & \text{otherwise} \end{cases}
\]

where \( \phi \in [0,1] \). It is reasonable to expect that the probability \( \phi \) is larger at the beginning of the iterative process and smaller towards the final iterations since at the beginning there is a higher chance that the hybrid HS procedure will converge to a new solution. Thus, a
dynamic updating scheme for $\phi$ is proposed, depending on the iteration number $k > 0$,
\[
\phi_k = \gamma_p \left( 1 - \frac{k}{k_{\text{max}}} \right)
\]  \hspace{1cm} (16)
where $\gamma_p \in (0, 1)$ is a constant and $k_{\text{max}}$ is the maximum number of iterations defined for the process. The smaller the parameter $\gamma_p$, the lower the likelihood that the search procedure in Algorithm 3 will move from $x$ to any of the other far away previously located minima. Since derivative information is not used in the search algorithm, the direction from $x$ to $\chi_i$ is considered to be ascent if $\mathcal{M}(x + \beta(\chi_i - x) - \mathcal{M}(x) > 0$ for a sufficiently small positive $\beta$. The pseudocode of the herein implemented MS method is presented in Algorithm 3 where $\Sigma$ denotes the set of the computed minimizers. To identify a solution that has not been previously located, $\chi \notin \Sigma$, one of the following conditions must hold: $\|x - \chi_i\| > \text{tol}$ or $\mathcal{M}(x) - \mathcal{M}(\chi_i) < \text{tol}$ for all $\chi_i \in \Sigma$, where $\text{tol}$ is a small tolerance.

There are two important issues that should be noted whenever the HS search procedure is invoked in the Algorithm 3. First, the region $\mathcal{B}$ from which the remaining HMS-1 points of the HM are randomly selected is a sphere centered at $x$ with a specified radius $R$. This way, the likelihood that the hybrid HS will converge to the nearest to $x$ minimizer (not yet located) is higher than that of any other far away previously located minimizer. Also, in the HS context, the (hyper-)box from which the new harmony $y$ is generated (see (11) and (12)) depends on the closeness of $x$ to $\chi_i$. If the likelihood of $x$ being inside the region of attraction of $\chi_i$ is high, the entire box is used; otherwise, a more restrictive box is defined $[\max \{l, x - R_o\}, \min \{l + R_o, u\}]$. Algorithm 3 is thus termed ‘sphere-based MS’ algorithm.

Although this type of algorithm is simple, it would not be effective if a stopping condition that precludes an exhaustive search of the search space is used. Besides allowing a reasonable number of iterations to be performed, $k_{\text{max}}$, the algorithm has an alternative stopping rule. The goal is to make the algorithm to stop when all roots have been located with certainty. Furthermore, it should not need to invoke the search procedure a large number of times to decide that all roots have been found. A simple condition uses an estimate of the fraction of uncovered space,
\[
U_k = \frac{r(r + 1)}{t(t - 1)}
\]
where $r$ is the number of different computed roots and $t$ represents the number of times the search procedure has been invoked [19]. The MS algorithm then stops if $U_k \leq \varepsilon$, for a small $\varepsilon > 0$.

Data: $k_{\text{max}}, \gamma_p \in (0, 1), \varepsilon < 1$, $\beta \ll 1$.
Set $\Sigma = \emptyset$, $r = 1$.
Randomly generate $x \in [l, u]$.
Set $\mathcal{B} = B(x, \frac{1}{2} \min \{u - l, l - u\})$.
Compute $\chi_1 = \text{HS}(x, \mathcal{B}, [l, u])$, set $t = 0$.
Compute $R_1 = \|x - \chi_1\|$, set $\Sigma = \Sigma \cup \chi_1$, set $k = 0$.

**Algorithm 3: ‘sphere-based MS’ Algorithm**

4 Numerical results

In this section, we investigate the performance of the proposed ‘sphere-based MS’ method that uses the hybrid HS algorithm as the search procedure on a set of benchmark small and large dimensional problems. They are listed below as Problems 1–10. We set the parameters of the algorithms as follows:

- in the MS algorithm: $\varepsilon = 0.05$, $\gamma_p = 0.5$, $\beta = 0.001$, $\text{tol} = 0.5e-2$ and $k_{\text{max}} = 30$ (unless otherwise stated);
- in the hybrid HS, HMS = $[2n, 5n]$, HMCR = 0.95, $F = 0.9$, $NI$ is set to depend on the problem ($NI = 10000$ in Problems 1, 2 and 6, $NI = 50000$ in Problem 3, $NI = 2000$ in Problem 7, $NI = 10000$ in Problems 4 and 5, $NI = 100000$ in Problems 8 and 9 and $NI = 200000$ in Problem 10), and $\lambda_{\text{best}}$ is identified as a global minimizer if the merit function value falls below $1e-10$. We consider $1e-08$ instead when solving Problems 8–10.
- in 1-HS, additionally to the values described above, PAR_{min} = 0.35, PAR_{max} = 0.99, BW_{min} = 0.000001 and BW_{max} = 5.
The experiments were carried out on a PC Intel Core 2 Duo Processor E7500 with 2.9GHz and 4Gb of memory. The algorithms were coded in Matlab Version 8.0.0.783 (R2012b).

4.1 Comparative tests with small dimensional problems

We now consider a set of seven small dimensional problems. First, we use three examples to illustrate the behavior of the ‘sphere-based MS’ algorithm when trying to locate multiple roots.

**Problem 1.** [14]: A simple nonsmooth nonlinear system with two roots \((-0.5, 0.5), (0.5, -0.5)\) in \([-3, 3]\):

\[ f(x) = \begin{cases} x_1^2 - x_2^2 = 0 \\ 1 - |x_1 - x_2| = 0 \end{cases} \]

Fig. 1 illustrates the method on the merit function to locate the two global solutions. The generated points correspond to a specific run with \(k_{\text{max}} = 10\) and five calls to the hybrid HS algorithm. Solution \((-0.500004, 0.500002)\) was obtained three times. The first time that the solution was located, the search procedure required 337 function evaluations (f.e.) and 0.019 seconds (sec.) to reach a merit value of 4.08e-11. PROCEDURE required 337 function evaluations (f.e.) and first time that the solution was located, the search procedure was invoked 13 times. The first located root \((0.000009, -1.999999)\) was reached twice and the first time \(0.707120, -1.499983\) was located twice, and the first point that was discarded and were not used to call the search procedure (magenta ‘\(\ast\’) and the initial points that converged in second (or in third) place to the solution (blue ‘\(\ast\’) and the points that were discarded and were not used to call the search procedure (magenta ‘\(\ast\)’). Overall, the ‘sphere-based MS’ algorithm required 2135 f.e. and 0.147 sec.

**Problem 2.** [10] This system of two nonlinear equations has three roots \((0, -2), (1, -1), (0.7071, -1.5)\) in \([-3, 3]\):

\[ f(x) = \begin{cases} x_1^2 - x_2 - 2 = 0 \\ x_1 + \sin\left(\frac{x_2}{2}\right) = 0 \end{cases} \]

Fig. 2 illustrates the ‘sphere-based MS’ on the merit function of Problem 2

The ‘sphere-based MS’ algorithm located three roots in 0.476 sec. and required 8526 f.e.. During this single run of 10 iterations, the hybrid HS search procedure was called five times.

**Problem 3.** [12] This is the Himmelblau problem and the number of roots in \([-5, 5]\) is nine:

\[ f(x) = \begin{cases} 4x_1^4 + 4x_1x_2 + 2x_2^2 - 42x_1 - 14 = 0 \\ 4x_2^4 + 2x_1^2 + 4x_1x_2 - 26x_2 - 22 = 0 \end{cases} \]

Fig. 3 shows the nine located roots and displays the merit function value and the number of function evaluations (inside parentheses) for each found root in a single run of the algorithm. The ‘sphere-based M S’ algorithm run for 30 iterations and the HS search procedure was invoked 13 times. The first located root (3.584428, -1.848126) with merit value of 9.999e-11 and after 0.858 sec. was located again in the third iteration. The second root was (-0.270845, -0.923039) with merit value of 4.44e-11 and after 0.848 sec. and was again recovered in the 7th, 10th, 13th, 17th, 18th and 29th iterations. The third root (-2.805118, 3.131312) with merit value of 9.94e-11 was located after 0.037 sec., the fourth was (0.000099, -1.999999) with merit value of 9.999e-11 and after 0.050 sec. with a merit value of 8.66e-11.
merit 9.92e-11 and 0.306 sec. (and recovered again in the 14th and 20th iterations), the sixth was (3.000000, 2.000000) with a merit value of 9.73e-11 and 0.441 sec., the seventh (0.086677, 2.884255) with merit 8.57e-11 was located after 0.664 sec. and the last two (3.385154, -0.306 sec. (and recovered again in the 7th (0.086677, 2.884255) with merit 9.92e-11 and 0.306 sec. (and recovered again in the 7th)

To analyze further the convergence performance of the proposed algorithm, 30 independent runs were carried out and the average values of three performance criteria – number of located roots, ‘n.r.’, number of function evaluations, ‘n.f.e.’, and CPU time in seconds, ‘time’ – are reported. The results produced by the algorithm are also compared with other heuristics. To analyze the effect of different HS variants as well as some parameter values on the algorithm’s convergence behavior, the next three tables contain the results of

Table 2: MS with $\mathcal{R} = [l, u]$, $\gamma_p = 0.5$: comparison of HS variants

Table 3 reports the results produced by the ‘sphere-based MS’ algorithm, in which the region $\mathcal{R}$ is a sphere and the constraint $[l, u]$ is always used as the search space to define the new harmony $y$, i.e., $(\tilde{l}, \tilde{u}) = (l, u)$ in all the three considered cases (see Algorithm 3). Results from the second, third and fourth columns correspond to $\gamma_p = 0.5$ and the remaining correspond to $\gamma_p = 0.05$. As previously stated, the lowest value of $\gamma_p$ yields fewer calls to the HS search procedure and consequently less function evaluations and smaller execution time. Thus, efficiency can be improved by reducing the value of the parameter $\gamma_p$. However, we

Table 3: MS with $\mathcal{R} = [l, u]$, $\gamma_p = 0.5$: comparison of HS variants

Besides the previously described, other small dimensional problems are the following.

Problem 4. (Application in robotic) [10] This equation has six roots in $[-1, 1]$

$$ k_0 + k_3x^2 + k_4x^4 + k_5x^6 + (k_1x + k_3x^3 + k_5x^5)\sqrt{1-x^2} = 0 $$

where $k_0 = 3.9852, k_1 = -8.8575, k_2 = -10.039, k_3 = 20.091, k_4 = 7.2338, k_5 = -11.177, k_6 = -1.17775.$

</table>

During these 30 runs, the two roots of Problem 1 were located by the ‘sphere-based MS’ algorithm in all runs. On average, each run of 30 iterations invoked the HS search procedure 11 times, required 7283 f.e. and 0.323 sec. to locate both roots, as reported in Table 4. However, the best run required 4003 f.e. and 0.183 sec. and the worst 9445 f.e. and 0.416 sec.

The ‘sphere-based MS’ algorithm located the three roots of Problem 2 in all runs. Fig. 2 displays the position of the roots in the search space \([-3, 3]^2\]. The HS search procedure was invoked on average 13.1 times, and the average number of f.e. and time were 15908 and 0.719 sec., respectively. The best run required 7159 f.e. and 0.320 sec. and the worst 21989 f.e. and 1.165 sec.

The nine roots of Problem 3 were located in two out of the 30 runs. The results displayed in Fig. 3 and reported above when describing Problem 3 were obtained in the best of these two runs. The algorithm found eight roots in 11 runs, seven roots in 13 runs and six roots in four runs. Considering the 30 runs, the hybrid HS algorithm was invoked on average 16.7 times and the average number of located roots, the average number of function evaluations and the average CPU time are reported in Table 4.

The six roots -0.999627, -0.880777, 0.483253, 0.876481, 0.958852 and 0.991557, with merit function values ranging from 4.86e-12 to 1.1e-10, of the Problem 4 have been identified in the best of the ten runs that located six different roots. The run invoked the HS procedure 10 times, required 75186 f.e. and 2.998 sec. The remaining 20 runs located five roots. On average, the HS search procedure was invoked 18.4 times, and the algorithm required 147664 f.e. and 5.345 sec.

When solving Problem 5 the two roots were located in all runs. The best run required 55119 f.e., 2.921 sec. and 11 calls to the HS procedure. The HS procedure needed 0.532 sec. to locate the root \((43.154623, 10.128917, 12.944063)\) with merit function 2.01e-09 and 0.188 sec. to locate \((-0.602990, 24.541978, 11.576714)\) with merit 6.97e-12. The worst of the 30 run invoked 15 times the HS procedure, required 106218 f.e. and 5.508 sec. Considering all the runs, the average number of calls to the HS procedure was 12.2 and the algorithm required an average of 83187 f.e. and 4.367 sec.

The two roots of Problem 6 were found in all runs. The best run invoked the HS procedure 6 times, lasted for 0.218 sec. and used 4722 f.e.; the worst invoked the HS procedure 15 times, lasted for 0.616 sec. and required 13824 f.e. During the best run, the root \((0.299447, 0.958852, 0.991557)\) with merit function 4.51e-11 was located after 582 f.e. and 0.026 sec. Overall, each run required on average 0.505 sec., 10968 f.e. and 0.416 sec.

† the reported solutions are not the global minimizers of \(\mathcal{M}\).
‡ only the best solutions are reported; one solution is outside \(\Omega\).
3.141595), (1.570776, 4.712411), (6.283185, 3.141584), (3.141589, 9.408e-07), and (4.712362, 1.570822) were obtained although not all in the same run. The best run that found 10 roots, invoked the hybrid HS algorithm 15 times, required 10148 f.e. and lasted 0.470 sec. The times required by the 10 calls to the search procedure that converged to the 10 different roots were 0.0009, 0.0002, 0.0003, 0.029, 0.094, 0.038, 0.0098, 0.0006, 0.094 and 0.094 sec. Nine roots were found in six runs, eight roots in 13 runs and seven roots in ten runs. The average number of roots found by the ‘sphere-based HS’ algorithm was 7.9 after 18857 f.e. and 0.881 sec. (see Table 4).

4.2 Problem with a large number of roots

We now aim to analyze the performance of the proposed ‘sphere-based HS’ algorithm when a large number of roots are present. The following problem is particularly interesting since the number of roots increases with the magnitude of the set $\Omega$.

**Problem 8.** [13] This problem is known as Effati-Grosan_1 and has been tested for different values of $a$ in the set $\Omega = [-a, a]^2$. Although the exact number of roots is unknown, it has been reported one root when $a = 2$, 13 roots when $a = 10$ and 127 when $a = 100$ [13]:

$$f(x) = \begin{cases} \cos(2x_1) - \cos(2x_2) - 0.4 = 0 \\ 2(x_2 - x_1) + \sin(2x_2) - \sin(2x_1) - 1.2 = 0 \end{cases} .$$

Table 5 reports the average results produced by Algorithm 3 when solving the three instances of Problem 8. We compare our results with two sets of results reported in [13]. These correspond to the best and the worst results obtained with different stopping rules in the MS algorithm. We remark that the therein used multistart approach is based on a quasi-Newton BFGS variant as local search procedure. Thus, the convergence speed is expected to be higher than that of our algorithm, since approximations to first and second derivatives are used.

On average, each run of 30 iterations invoked the HS search procedure 9 times, required 10785 f.e. and 0.623 sec. to locate one root of the instance identified with $a = 2$, as reported in Table 5. When solving the instance with $a$ set to 10, we allowed the Algorithm 3 to run for a maximum of 200 iterations. On average, the HS search procedure was invoked 59 times and an average of 12.5 roots were found. The best run of the set found the 13 roots after invoking the HS procedure 61 times, where each one required an average of 4406 f.e. and 0.258 sec., and a merit value of 3.528e-09. Finally, when the instance with $a = 100$ was solved, the algorithm was allowed to run for a maximum of 500 iterations, invoked on average the HS search procedure 364.6 times and was able to locate on average 117.2 roots. The best run found 120 roots after invoking the HS procedure 360 times, where each one required on average 36155 f.e. and 1.992 sec., with a merit function value of 3.524e-09.

4.3 Tests with large dimensional problems

To analyze the convergence behavior of the Algorithm 3 when solving large dimensional problems, we use two problems with varied dimensions. With each problem we test the algorithm with the following dimensions 10, 20, 30, 40.

**Problem 9.** [13] This is the Yamamutra problem that has three roots in $[-2, 2]^2$, and it can be tested for different values of $n$:

$$f_i(x) = x_i - \frac{1}{2n} \left( \sum_{j=1}^{n} x_j^3 + i \right) = 0, i = 1, \ldots, n.$$  

Table 6 reports the average results produced by Algorithm 3 when solving the four instances of Problem 9. We also report the results available in [13] for comparison. The ‘emphasized’ values inside parentheses show the average number of function evaluations and the average time in seconds required by each call of the HS search procedure. Besides the criteria ‘n.r.’, ‘n.f.e.’ and ‘time’, the table also shows the ‘HMS’ value used in these experiments. When solving the instance with $n = 10$, the HS procedure was invoked an average of 10.4 times and the average number of located roots was 2.6. On the other hand, when solving the instance with $n = 20$, the HS procedure was invoked an average of 10.9 times and the average number of located roots was 2.4. When solving the instance with $n = 30$, the best run found the 3 roots after 16 calls to the HS procedure. Overall the averaged values of the three criteria are 1.4 (’n.r.’), 2.1e+06 (’n.f.e.’) and 614.04 (’time’), as shown in Table 6. Finally, when setting $n = 40$ in Problem 9, the algorithm located an average of 1.5 roots, after 9.4 calls to the HS search procedure, and required 3.0e+06 f.e. and 1077.1 sec. Further, the best run that found 3 roots required 5.18e+06 f.e., 1.82e+03 sec. and invoked 16 times the HS procedure.

**Problem 10.** [27]: Consider the Broyden tridiagonal system, a frequently used problem for testing sensitivity to provided initial approximations, which has been tested for different values of $n$ and has one root in $[-1, 1]^n$:

$$f(x) = \begin{cases} f_1(x) = (3 - 2x_1)x_1 - 2x_2 + 1 = 0 \\ f_2(x) = (3 - 2x_2)x_2 - x_1 - 1 - 2x_{i+1} + 1 = 0, i = 2, \ldots, n - 1 \\ f_n(x) = (3 - 2x_n)x_n - x_{n-1} + 1 = 0 \end{cases} .$$

Table 7 reports the average results produced by Algorithm 3 when solving the four instances of Problem 10 (when n is set to 10, 20, 30, 40). This table also includes the average number of calls to the HS procedure, ‘n.calls’. With this example we aim to analyze the effect of the size of the harmony memory in the hybrid HS-based algorithm. We note here that the root was found in all runs whatever the instance and HMS. From the results we conclude that the HMS does not affect the performance of the ‘sphere-based HS’ algorithm.

According to the results presented in the last four tables, we may conclude that the proposed ‘sphere-based MS’ algorithm is able to locate multiple roots of small as well as large dimensional systems of nonlinear equations. Since the hybrid HS-based search procedure does not require any derivative information, the algorithm is general-purpose and can be applied even to nonsmooth problems.

5 Conclusions

In this paper, a hybrid HS-based MS method to compute multiple roots of a system of nonlinear equations has been presented. The method, denoted by ‘sphere-based MS’ algorithm, relies on some new ideas aiming to increase the exploration power of an MS algorithm and enhance the exploitation of more restrictive regions of the search space. The search procedure that is invoked in the MS paradigm is a global search algorithm from the metaheuristic class. The name ‘hybrid HS’ algorithm comes from the hybridization of a classical HS algorithm with a mutation operator present in the DE algorithm. Furthermore, self-adaptive rules for the parameters PAR and BW of the pitch adjustment operator are proposed. The main differences between the proposed MS-type algorithm and the others in the literature lie in the regions that are provided to the search procedure to look for a new solution (instead of the usual search space Ω). In the HS context, those regions that are used to create the HM are spheres centered at the sampled point with appropriate radius. Further, the new harmony is generated inside a box that may coincide with the given box constraints of the problem or a more restrictive box, depending on the position of the sampled point relative to the previously located solutions. From the numerical experiments carried out with a set of ten benchmark small and large dimensional problems we may conclude that the proposed ‘sphere-based MS’ algorithm with the hybrid HS search procedure is effective in locating multiple roots and competitive when compared with other metaheuristics.
