21   **Abstract**

22   *Purpose*: Nowadays, the percutaneous renal access (PRA) is planned and guided by

23   the independent evaluation of different pre- and intraoperative images, such as

24   computed tomography (CT), ultrasound (US) imaging and fluoroscopy, notably

25   increasing the difficulty of the intervention and requiring great operator expertise. As a

26   crucial step in accessing the kidney in several minimally invasive interventions, PRA

27   practicality and safeness may be improved through the fusion of CT and US data.

28   Therefore, this work aims to assess the potential of an enhanced image-guided

29   framework to PRA by fusion the US and CT data through a surface-based registration

30   technique.

31   *Methods*: Ten porcine kidney phantoms with fiducial markers were imaged using CT

32   and 3D US. Both images were manually segmented and aligned to create a ground-

33   truth. In a virtual simulated and controlled environment, 2D contours were extracted by

34   slicing the 3D US kidney surfaces from a single-oriented acquisition and using usual

35   PRA US-guided views, while the 3D CT kidney surfaces were misaligned to simulate

36   positional variability. The surface-based registration was assessed using two state-of-

37   the-art methods of the iterative closest point algorithm (*point-to-point*, ICP1; and *point-

38   to-plane*, ICP2) and three hypotheses were studied: i) use of single-plane (transverse

39   view, SP_T; and longitudinal view, SP_L) *versus* bi-plane imaging (BP); ii) use of multiple

40   planes acquired by an US probe's sweep; and iii) influence of US probe's sweep

41   movements during acquisition.

42   *Results*: SP_L and BP acquisitions had the best performance when multiple planes and

43   ICP2 method were used. The average point-to-point distance between registered US

44   and ground-truth surfaces for SP_L and BP were 2.47 mm and 2.48 mm, respectively.

45   Focusing on the US probe's sweep movements, a large sweep along the central

46   longitudinal view presented the best results for SP_L, with an average point-to-point

47   distance of ~2 mm.

48   *Conclusions*: This is the first study that assesses the optimal 2D US acquisition

49   protocol to improve surface-based registration between CT and US data for image-

50   guided PRA. Therefore, multiple slices and specific sweep movements may be crucial

51   to improve final registration. Surface-based registration is here suggested as a valid

52   strategy for intraoperative image fusion using CT and US data. This strategy has the

53   potential to be applied to different image modalities and interventions, and the

54   presented methodology has the potential to be used to assess their feasibility.

55

1 INTRODUCTION

Percutaneous renal access (PRA) is a surgical step where the surgeon inserts a surgical needle from the skin until the kidney target site. It is used in several minimally invasive kidney interventions (MIKI), such as percutaneous nephrolithotomy, kidney radiofrequency ablation of renal tumors, and kidney biopsies. During MIKI, medical imaging is crucial in two distinct phases: the surgical planning, which usually relies on preoperative computed tomography (CT) data; and the PRA, which is generally performed under intraoperative imaging guidance [1,2]. Fluoroscopy and two-dimensional (2D) ultrasound (US) are the most common modalities for PRA, providing a real-time depiction of the renal system and instruments. However, since fluoroscopy requires radiation exposure, pure US image guidance appeared, recently, as a potential and attractive solution. Besides avoiding radiation, US has been shown to present other advantages over fluoroscopy, including shorter puncture time, higher success rate of first puncture, less blood loss, and fewer complications [3].

The surgeon's ability to visualize and reach the anatomical target during PRA delimits the MIKI success. The ideal PRA is one that allows a safe and precise access to the kidney target site while minimizing bleeding. Therefore, PRA remains a challenging task for surgeons [4]. Inaccurate and multiple needle punctures often cause complications [1,5], where injuries to kidney or contiguous organs can eventually prejudice the surgical outcome.

To overcome the abovementioned drawbacks, many paths and technological advances have been proposed to improve PRA [6]. Recently, PRA was performed with excellent results using ureteroscopy and an electromagnetic tracking system [7,8]. However, the authors mentioned the lack of visualization of anatomical structures in real-time during puncturing as an important disadvantage. In the past few years, concepts of enhanced image-guided interventions (eIGI) have been studied for PRA. eIGI are computer-

based systems that overlap different imaging data to improve the physicians' perception of the target site. In this sense, anatomical information from preoperative images - such as CT or magnetic resonance imaging (MRI) – are fused with real-time intraoperative US images, allowing to enhance the latter with preoperative planning information [9–16].

One of the fundamental steps of eIGI is the registration between the preoperative and intraoperative image data, bringing them to the same coordinate system. Several registration methods have been presented in the literature for eIGI, including landmark-based, intensity-based and segmentation-based methods [17–19]. Despite the primacy of intensity-based registration methods in the past few years [18], segmentation-based followed by surface alignment has been shown to be more successful than landmark-based and intensity-based when the images present low quality or missing data [19]. Moreover, surface-based alignment methods are computationally attractive solutions, because they become independent of the image after segmentation and, usually, reduce the number of data under processing.

Previous works have tried to fuse 2D US with preoperative data for MIKI based on surface-based registration. Ahmad *et al.* proposed to individually segment arbitrarily placed and oriented US slices using an optical tracker coupled to a laparoscopic US probe [20]. Based on the spatial location of the US probe, the three-dimensional (3D) surface of a kidney tumor phantom is reconstructed using two different segmentation approaches. Differences were measured after registration of the reconstructed surfaces with the ideal reference, corroborating the added-value of this strategy. Mozer *et al.* used multiple and sparse transverse and longitudinal contours to align US and CT data [13]. Li *et al.* used two pairs of orthogonal US slices to register with a MRI model [12]. In addition, the authors presented a respiratory gating technique to compensate organ motion. The same authors presented a different approach based on statistical shape model, which was used to reconstruct kidney surfaces using sparse points from US

images [14]. Finally, Seo *et al.* used two orthogonal 2D US probes to create a bi-plane US imaging of the kidney and, then, estimate the pose of a preoperative 3D model [21]. The proposed method showed high accuracy and robustness, being tested in different applications [22–24]. Overall, the previous works demonstrated that surface-based registration allows to achieve good results. However, most of them acquired 2D US images from arbitrary and sparse longitudinal and transverse views, using different strategies to maintain continuous and feasible registration, as respiratory gating, a simultaneous acquisition using two US probes, and robot motion compensation, which are not always accurate and practical to perform within the operating room.

Due to the improvements in real-time image processing, namely in segmentation [25], in tracking [26], and in general computational capabilities [27,28], the continuous registration and monitoring of medical images is now possible. Notwithstanding, imaging should also be continuous to perform continuous organ monitoring. Since the direct access to online US raw data is restricted by most manufacturers, the usual approach is to grab the real-time data displayed on the screen, being therefore restricted to a 2D image view. Taking this into account, this work aims to assess the accuracy of surface-based registration between CT and 2D US images for image-guided PRA. Thus, this work intends to answer three practical hypotheses:

- *Hypothesis 1*: Can the use of bi-plane slices from four-dimensional (4D) probes (orthogonal images), when compared to 2D probes, benefit the registration between US and CT kidney surfaces?
- *Hypothesis 2*: Can the use of multiple slices (acquired by sweeping the probe) benefit the registration between US and CT kidney surfaces?
- *Hypothesis 3*: Can different US probe's sweep movements (acquiring kidney slices at different positions) benefit the final alignment between US and CT kidney surfaces?

137 This paper is structured as follows. In section 2, we present our experimental setup,

138 which is based on phantoms manufactured for CT and US imaging for image-guided

139 PRA. Additionally, we present our experimental design, which explains how the

140 manually segmented 3D phantom models from CT and US are used to virtual simulate

141 2D US acquisitions in a controlled environment, as well as describes the different

142 registration methods used in the assessment. In section 3, we present the results,

143 which are discussed in section 4. In section 5, we present the main conclusions of our

144 study.

145

146 2 MATERIALS AND METHODS

147 2.1 Experimental setup

148 2.1.1 Phantom preparation

149 Phantoms were constructed using the protocol presented in Gomes-Fonseca *et al.* [29].

150 In short, the phantom was manufactured based on a porcine kidney combined with

151 tissue mimicking material (TMM) and implanted fiducial markers (FMs), see Figure 1-A.

152 While the TMM mimics the surrounding tissues of the kidney, the FMs are used to

153 accurately align both US and CT images (Figure 1-B). Overall, ten phantoms were

154 built.

155

156 2.1.2 Image acquisition

157 The CT images were acquired using a Philips Brilliance 64 CT scanner (Philips

158 Healthcare, Best, The Netherlands). The X-ray tube current and peak voltage were set

159 to 313 mA and 120 kV, respectively. The abdomen protocol was selected. On average,

160 the CT volume size was 512x512x300 with a voxel resolution of $0.701 \times 0.701 \times 1$ mm.
Figure 1 – (A) A porcine kidney phantom model with implanted fiducial markers (FMs). The image represents the phantom cut in half. (B) Ground-truth. Images and segmented surfaces from both CT and US volumes of a kidney phantom model. Images are aligned based on selected (FMs). CT images, surfaces and associated FMs are represented by gray level images, green surfaces and points, respectively, while yellow and red are used to represent US images, surfaces and points.

161   The US images were acquired using a Voluson P6 US system (GE Healthcare,

162   Milwaukee, Wisconsin, USA). The 4D convex abdominal transducer (RAB2-6-RS, 2-5

163   MHz) was used. According to the machine settings, 3D images were acquired using

164   the high-quality mode (setting: high2), the maximum field-of-view (setting: B90º/V85º)

165   and a depth of 15.9 cm. The voxel resolution was $0.667 \times 0.667 \times 0.667$ mm with a

166   volume size of $235 \times 172 \times 197$.

167

168   2.2   Experimental design

169   2.2.1   Data preparation

170   Two segmented 3D surfaces were initially created for each phantom, namely one using

171   the CT images, and another based on the US images. In detail, the CT volume was

172   delineated using the 3D Slicer software (version 4.6). The files from the 3D US system

173   were initially converted to Meta Image files using BabyOSlice software (Tomovision,

174   Canada), and were then uploaded to the 3D Slicer software and manually delineated.

175   In both cases, the manual delineation relied on multiple 2D contours followed by 3D

176   interpolation to obtain the final 3D surface.

177 In addition, the implanted FMs were manually detected on both CT and US volumes of
178 each phantom (Figure 1). Note that the FM are visible as brighter and darker structures
179 in US and CT images, respectively. The detected FMs were then aligned based on the
180 strategy presented by Horn *et al.* [30] (using the image-guided therapy toolbox available
181 on 3D Slicer), establishing the ground-truth alignment between both surfaces.

182

183 2.2.2   Data simulation

184 To virtually simulate the normal variability found throughout an intervention, both in
185 terms of US field-of-view and anatomical kidney positioning, the experimental data was
186 simulated in two independent stages: 1) simulation of the variability associated with the
187 probe position/orientation wrt. the patient's body in the operative room (section
188 2.2.2.A); and 2) simulation of the anatomical positional variability of the preoperative
189 data (section 2.2.2.B).

190

191 *A. Simulation of intraoperative kidney acquisition and segmentation of 2D US images*
192 According to Chu *et al.* [31], during US-guided PRA, the US probe is typically positioned
193 to capture longitudinal and/or transverse sections of the kidney (Figure 2). Thus, in
194 these experiments, the kidney's central *longitudinal* and *transverse* sections were
195 defined, per convention, to be aligned with the *xz* and *xy planes*, respectively (Figure 3-
196 A). The US probe was virtually positioned 6 cm away from the center of the kidney US
197 surface, mimicking the typical distance between kidney and skin [31], and the center of
198 rotation defined at the probe's tip (Figure 2).

199 Multiple 2D US slices and their respective 2D contours were generated by reformatting
200 the original volume and surface. In this sense, multiple rotations (i.e., *roll*, *pitch*, and
201 *yaw*) of the central *longitudinal* and *transverse* planes (Figure 3-A) were applied.
202 Henceforth, the rotations linked to US imaging will be designated as $roll_{US}$, $pitch_{US}$,
Figure 2 – Representation of single-plane acquisition for *longitudinal* (SP_L) and *transverse* (SP_T) *views*, and bi-plane (BP) for *both* views in a virtual simulated and controlled environment. Surface-based registration for image-guided percutaneous renal access is assessed based on these probe views. A single-oriented acquisition fixed on the center of rotation is performed, mimicking a continuous imaging of the kidney.

203   and yaw_{US}, each representing a different simulated probe sweep movement and

204   respective 2D contours wrt. the kidney.

205

206   *B. Simulation of preoperative CT kidney surfaces' positional variability*

207   The anatomical positional variability expected before surface-based registration was

208   simulated by applying transformations to the CT surface. The idea is to mimic the

209   different orientations that the kidney can have before the fusion, which affect the initial

210   alignment between modalities. These differences are usually related to the patient's

211   body positioning during preoperative and intraoperative acquisitions. As performed

212   above, changes in *roll*, *pitch*, and *yaw* orientations were applied wrt. the CT kidney

213   surfaces' center. The different orientations were applied in pairs following the Euler

214   convection (*yaw-pitch-roll*), namely *pitch-roll*, *yaw-roll*, and *yaw-pitch.* This split

215   intended to simplify the evaluation, while maintaining a complex misalignment between

216   volumes. Nineteen rotations were performed per orientation, ranging from -90⁰ to 90⁰

217   with 10⁰ increments. Each pair created 361 misaligned surfaces, in a total of 1083 per

218   phantom. Then, to simplify the results' interpretation, pairs with equal changes in

219   orientation were combined. Henceforth, changes in orientation of the CT surfaces are

220   termed as $roll_{CT}$, $pitch_{CT}$, and yaw_{CT}.

221

222   2.2.3   Registration algorithms

223   The tests were performed assuming rigid transformation models between surfaces.

224   The iterative closest point (ICP) algorithm was used to estimate point correspondences

225   between point clouds and compute the optimal transformation between them [32–34].

226   Usually, ICP is a fast technique, which is very important for image-guided interventions.

227   In this work, two state-of-the-art variants of *error metric* were used:

228   1) the *point-to-point* error metric that sums the squared distances of source points to

229   target points:

$$R, t \leftarrow \arg\min_{R,t} \sum_{i=1}^{N} \|(Rp_i + t) - q_i\|^2 \tag{1}$$

230   where p_i is a source point and q_i a corresponding point in the target point cloud, while

231   R is the rotation matrix and t is the translation vector that minimizes the distance

232   between source and target. A closed form solution for the minimization of the *point-to-*

233   *point* error metric is the Singular Value Decomposition (SVD) algorithm [35,36].

234   Henceforward, this variant is termed ICP1.

235   2) and, the *point-to-plane* error metric that sums the distances of source points to the

236   surface normal in which the matched target points reside:

$$R, t \leftarrow \arg\min_{R,t} \sum_{i=1}^{N} \|((Rp_i + t) - q_i) \cdot n_i\| \tag{2}$$

237   where n_i denotes the estimated surface normal at q_i. The only closed form solution for

238   the minimization of the *point-to-plane* error metric is after linearization of the rotation

239   matrix [35,36]. Henceforward, this variant is termed ICP2.

240   Finally, throughout these experiments, the CT surface was defined as the target point

241   cloud, with the US surface being the source point cloud. For both variants, a fixed

242   number of iterations were applied (25 iterations were used in the current experiments).
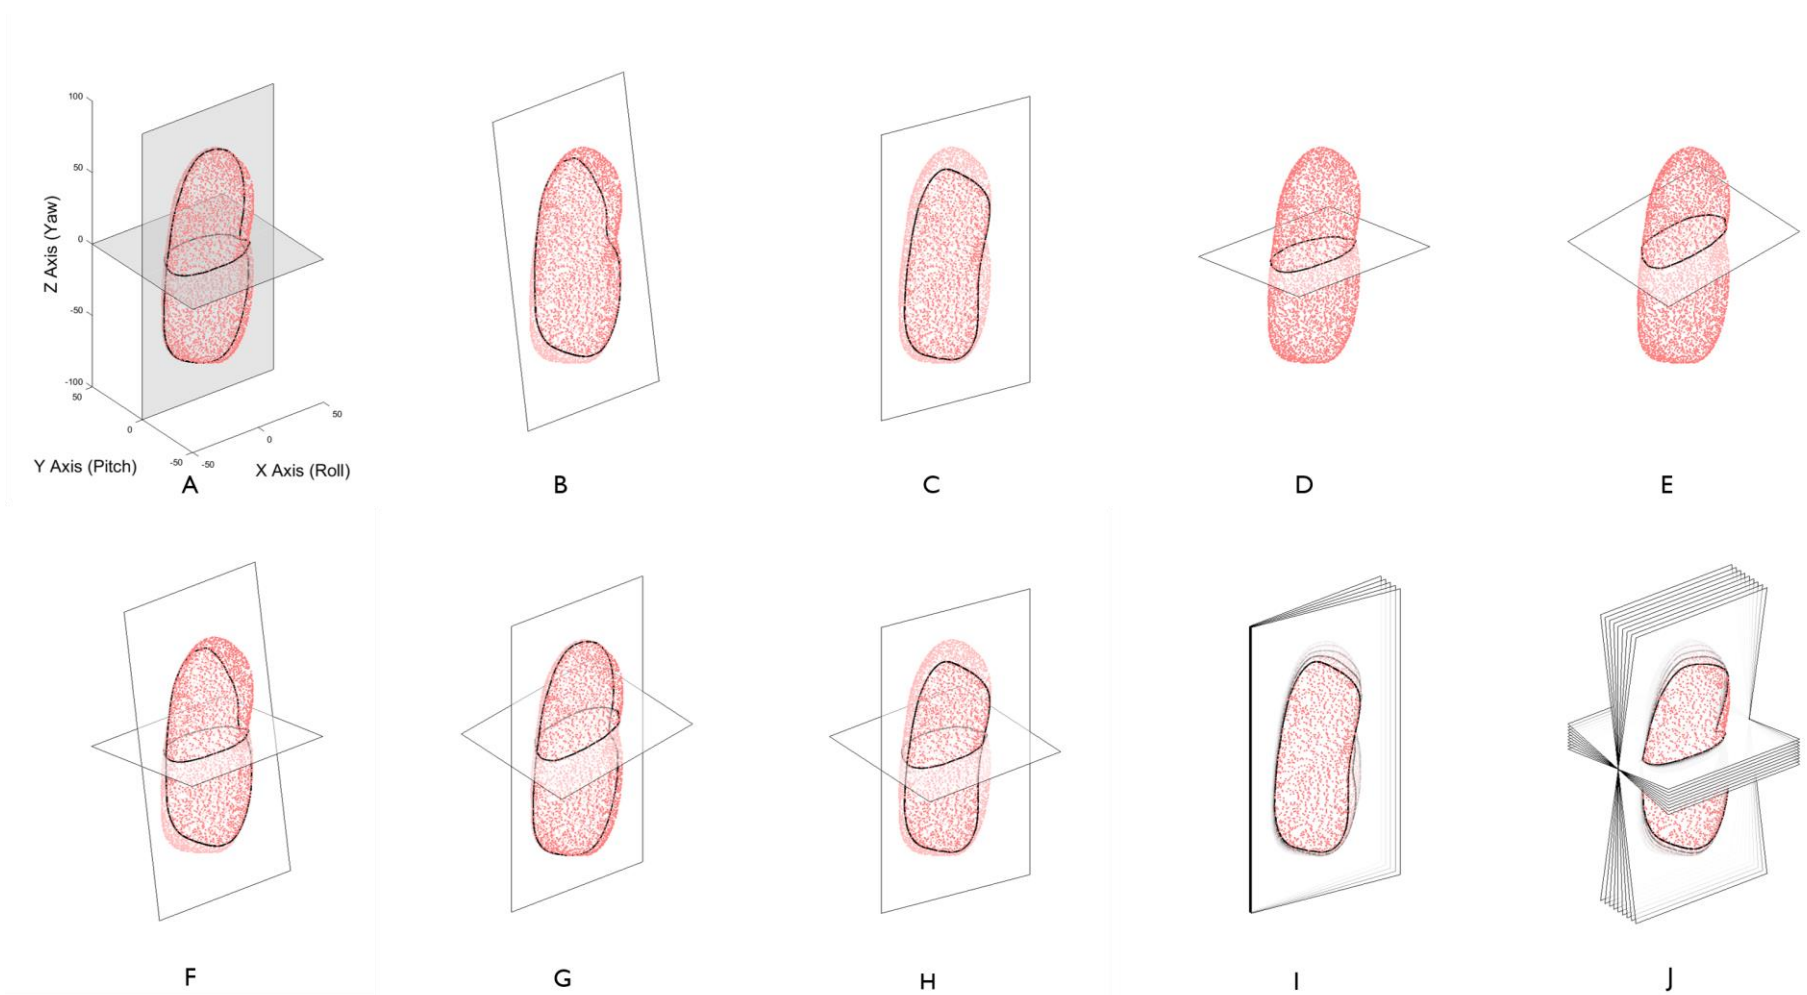

Figure 3 – Examples of kidney slicing simulation. (A) Central *longitudinal* and *transverse* views. SP_L rotated in (B) $roll_{US}$, and (C) yaw_{US} (rotation: -10º). SP_T rotated in (D) $roll_{US}$, and (E) $pitch_{US}$ (rotation: -10º). BP rotated in (F) $roll_{US}$, (G) $pitch_{US}$, and (H) yaw_{US} (rotation: -10º). (I) SP_L using multiple slices in yaw_{US} (5 slices). (J) BP using multiple slices in $roll_{US}$ (9 slices). All images were captured with the same view.

243

244   2.2.4   Experiments

245   The experiments were designed focused on the three abovementioned hypotheses:

246   *Hypothesis 1* was performed by testing the registration performance of *longitudinal* and

247   *transverse* slices (single-plane acquisitions), as well as the case in which *both* slices

248   are used together (bi-plane acquisitions). These two options test the use of both 2D

249   and 4D US probes, simulating the grabbing of the real-time data displayed on the

250   screen (as the direct access to online US raw data is restricted). To simplify the

251   reading, single-plane acquisitions from longitudinal slices will be designated as SP_L;

252   single-plane acquisitions from transverse sections as SP_T; and bi-plane acquisitions as

253   BP.

254   *Hypothesis 2* attempted to verify if multiple and sparse contours of the kidney, obtained

255   by sweeping the probe from a single-oriented acquisition, can improve the registration

256   between US and CT kidney surfaces.

257   *Hypothesis 3* attempted to verify if different movements of the US probe during an

258   acquisition can improve the registration between US and CT kidney surfaces.

259   According to the US probe's center of rotation, $roll_{US}$, $pitch_{US}$, and yaw_{US} simulate

260   different movements that differently slice the kidney.

261   Since these three hypotheses are intrinsically linked, different parameters were varied

262   together. Thus, SP_L, SP_T, and BP were transformed using their central planes as

263   references. Therefore, -10º to 10º with increments of 2.5º were used along the $roll_{US}$,

264     $pitch_{US}$, and yaw_{US} orientations. Each slice originated a specific contour. Moreover,

265   these contours were sequentially combined in sets of one, two, five or nine contours.

266   Finally, each set of contours was registered against all *misaligned CT surfaces* for each

267   phantom. Furthermore, the experiments tested both variants of the ICP algorithm.

268   It is important to mention that SP_L originates different contours when changing $roll_{US}$

269   and the yaw_{US} (Figures 3-B and 3-C), while SP_T the $roll_{US}$ and the $pitch_{US}$ (Figures 3-D

270   and 3-E). Similarly, BP originates different contours when changing $roll_{US}$, $pitch_{US}$, and

271   yaw_{US} (Figures 3-F, 3-G and 3-H).

272

273   2.3   Error metrics and statistical analysis

274   As abovementioned, FMs were used to establish the *ground-truth alignment* between

275   CT and US images. In this sense, the fiducial registration error (FRE) describes the

276   error inherently associated with the ground-truth itself. During experiments, all applied

277   transformations (sections 2.2.2.A and 2.2.2.B) assumed the *ground-truth alignment* as

278   the reference position.

279   Next, to assess the errors after registration, two surfaces were used, namely the

280   *misaligned CT surfaces* and the *misaligned US surfaces*. Both surfaces were equally

281   rotated applying the transformations described in section 2.2.2.B. While the *misaligned*

282   *CT surface* represents the errors between image modalities, the *misaligned US surface*

283   represents the ground-truth position that should be found upon the registration process.

284   Indeed, the registration process computes the transformation from US contours (from

285   section 2.2.2.A) to the *misaligned CT surface*, and then this transformation is used to

286   obtain the *registered US surface.*

287   All metrics were computed using the 3D surfaces and volumes. Therefore, the average

288   distance (AVD), the Hausdorff distance (HD), and the Dice similarity coefficient (DSC)

289   were used to measure the differences between *misaligned CT surface* and *registered*

290   *US surface*, whereas the average point-to-point distance (P2P) and maximum angle

291   error (MAE) measured the differences between the *misaligned US surface* and

292   *registered US surface.* The performance was assessed by comparing the error metrics

293   (AVD, HD, DSC, P2P, and MAE) across different scenarios.

294   All statistical tests were conducted using MATLAB® (version R2016b, The Mathworks

295   Inc., Natick, MA). The assumption of normality was assessed for all variables and,

296   according to the results, parametric or nonparametric tests were applied accordingly.

297   The effect size and statistical significance were reported. All statistics were considered

298   significant if $p < 0.05$.

299

300   3 RESULTS

301   3.1 General observations

302   Due to the non-normal distribution of the computed metrics, all results are presented

303   using the median and the interquartile range (IQR). Moreover, non-parametric

304   statistical tests were performed to compare different scenarios.

305   All ten phantoms were successfully produced and imaged. These models were aligned

306   using the correspondent FMs selected on both images. On average, FRE was 0.98

307   (0.21) mm, indicating a close alignment between US and CT images and validating the

308   ground-truth used. Respectively, DSC, AVD, and HD were 90.40 (4.16) %, 1.77 (0.28)

309   mm and 4.83 (1.41) mm, reinforcing the high accuracy of this stage.

310

311   3.2 *Hypothesis 1*

312   SP_L and BP revealed better performance than SP_T during surface-based registration.

313   Respectively, the average P2P distance for SP_L, SP_T and BP was 8.09 (8.34) mm,

314   27.10 (22.61) mm, and 6.30 (8.15) mm using ICP1; and 8.41 (40.53) mm, 41.84

315   (32.55) mm, and 3.77 (2.79) mm using ICP2 (1 slice, see Table 1). The differences

316   between SP_L, SP_T and BP were statistically significant for both ICP methods ($p < .001$).

317   Pairwise comparisons revealed that all groups were statistically different ($p < .05$).

318

Table 1 – Results of multiple slices acquisitions using *Longitudinal* (SP_L), *Transverse* (SP_T) and *Both* (BP) views. Two iterative closest point methods are presented (ICP1 – point-to-point error metric; ICP2 – point-to-plane error metric), and five different metrics are computed. Dice similarity coefficient (DSC); average distance (AVD); 95th Hausdorff distance (HD); average point-to-point distance (P2P); and maximum angle error (MAE). All metrics are represented by median (IQR), being the statistical test performed also indicated. Best values are in bold. *Pairs of slices.

319

320   3.3   *Hypothesis 2*

321   Table 1 summarizes the results obtained when using multiple slices. The results show

322   that errors decrease when the number of slices used increases in SP_L, SP_T and BP ($p <$

323   .001). This fact was observed in all metrics and in both ICP methods.

324   The lowest errors were obtained when nine slices were used to create a sparse 3D

325   model of the kidney, with the ICP2 method being used. It is important to highlight that

326   similar errors were obtained by SP_L and BP. Indeed, median values of DSC, AVD, HD,

327   P2P and MAE were respectively 90.71%, 1.72 mm, 4.13 mm, 2.48 mm and 2.59⁰ for

Figure 4 – Results of ICP2 method for one and nine slices acquisitions wrt. different CT misalignments. A line graph is used to represent the average P2P distance for each CT model misalignment. Each dot symbol illustrates the median/IQR value of all registrations. Lines represent different views used (SP_L, SP_T, and BP). Left graphs: Median values. Right graphs: Interquartile range (IQR) values. *Pairs of

328   BP, and 90.62%, 1.80 mm, 4.22 mm, 2.47 mm and 2.99º for SP_L. In addition, both

329   variants presented similar DSC, AVD, and HD errors when compared to the ground-

330   truth (section 3.1).

331   Figure 4 presents the median and IQR of average P2P distance for each angle applied

332   to misalign the CT model, i.e. $roll_{CT}$, $pitch_{CT}$, and yaw_{CT}. These graphs describe the

333   errors for SP_L, SP_T and BP, when using either one or nine slices for surface-based

334   registration. SP_L and BP had the best registration performance when 9 slices were

335   used. Misalignments over ± 50º on the CT surface were typically associated with higher

336   errors.

338 ### 3.4 *Hypothesis 3*

339 Considering the previous results, Figure 5 shows the influence of different US probe

340 movements ($roll_{US}$, $pitch_{US}$, and yaw_{US}) when SP_L and BP acquisitions with 9 slices

341 were used. The results revealed that using yaw_{US} movements together with a SP_L

342 acquisition presented lower errors, independently of the CT kidney orientation (i.e. for

343 different CT misalignments, namely $roll_{CT}$, $pitch_{CT}$, and yaw_{CT}). Close values were

344 obtained for the BP acquisition. However, BP presented lower IQR values, showing

Figure 5 - Results for different US sweep probe movements ($roll_{US}$, $pitch_{US}$, and yaw_{US}) applied for both SP_L, and BP views. Graphs show results of using 9 slices for ICP2 method. Lines graphs with average P2P distance associated to each CT model misalignments. Each dot symbol illustrates the median/IQR value of all registrations. Left graphs: Median values. Right graphs: Interquartile range (IQR) values.

345   lower variability. The $pitch_{US}$ movement together with BP acquisition presented the

346   worst results.

347   Due to the positive results of yaw_{US}, this US probe's sweep movement was further

348   explored by capturing different zones of the kidney. Figure 6 describes the results of

349   sweeping the kidney in different extremes using yaw_{US} movements, dividing them into

350   a set of slices. The median differences between BP and SP_L were small, being slightly

351   better for SP_L in Set2 and Set3. The lowest median values were obtained with the

352   central set (i.e. Set3) for both BP and SP_L. In addition, the minimum values were

353   obtained when the central longitudinal slices were captured (i.e. Set2, Set3, and Set 4).

354   Again, BP presented a lower variability than SP_L.

355

Figure 6 - Results of using yaw_{US} movement during 2D US acquisition for SP_L and BP. Boxplots show the results for different set of slices according to different slicing angles, namely Set1: [-10º -7.5º -5º -2.5º 0º]; Set2: [-7.5º -5º -2.5º 0º 2.5º]; Set3: [-5º -2.5º 0º 2.5º 5º]; Set4: [-2.5º 0º 2.5º 5º 7.5º]; Set5: [0º 2.5º 5º 7.5º 10º]. Set1 and Set5 represent the extremes of slicing, while Set3 the central one. Each set is represented by top views with the corresponding slices. Boxplots represent de minimum, first quartile, median, third quartile, and maximum of the P2P distance.

4 DISCUSSION

356

357 In this work, we studied the feasibility of two surface-based registration approaches for

358 fusing 2D US and CT data to facilitate PRA procedures. The different approaches were

359 tested using kidney phantom models and hundreds of thousands of surface-based

360 registrations were performed, allowing an accurate evaluation of the algorithm's

361 performance. In addition, manual segmentation of both image modalities simulated

362 common differences between US and CT segmentation methods. This detail reinforces

363 the results obtained in the present work since these differences demanded more from

364 the registration process. To the best of our knowledge, this is the first study that

365 assesses the optimal 2D US acquisition protocol to improve surface-based registration

366 between 2D US and CT data for image-guided PRA. Thereby, three hypotheses were

367 studied.

368 Hypothesis 1 with the question: "*Can the use of bi-plane slices from 4D probes*

369 *(orthogonal images), when compared to 2D probes, benefit the registration between*

370 *US and CT kidney surfaces?*", revealed that, globally, bi-plane acquisitions had better

371 performance during surface-based registration. This is expected since more details of

372 the kidney anatomy are captured (i.e. orthogonal images are acquired), which

373 ultimately enhances the performance of the ICP method to automatically align

374 intraoperative and preoperative spaces. Overall, the method performance is

375 comparable to other state-of-the-art solutions using a similar orthogonal US images

376 acquisition approach. *Seo et al.* reported an error of 1.68 mm in one phantom model

377 (with biplane acquisition at the surface's center using two orthogonal 2D probes), and

378 our study obtained an error of 2.01 mm (AVD for 1 slice BP, see Table 1) with higher

379 anatomical variability. Moreover, it is relevant to mention that our initial ground-truth

380 error between preoperative CT surface and intraoperative US surface was, on average,

381 1.77 mm (based on FMs), while Seo *et al.* assumed as gold-standard the registration of

382 the preoperative surface with multiple biplane US contours. The concept of real-time

383   biplane US imaging has been also used in other medical fields, particularly in

384   cardiology, with good outcomes. Lang *et al.* evaluated the accuracy and robustness of

385   a surface-based registration method for intraoperative use. They found that the use of

386   bi-plane contours had the best accuracy wrt. other approaches, with registration errors

387   lower than 5 mm, even in clinical data [37]. The same authors also showed the potential

388   of surface-based registration use in real-time image-guidance [38].

389   Considering in more detail Hypothesis 2: *"Can the use of multiple slices (acquired by*

390   *sweeping the probe) benefit the registration between US and CT kidney surfaces?",* it

391   was possible to observe a superior performance of the registration method when

392   multiple slices were used. SP_L and BP shown similar registration errors when nine

393   slices were used (see Table 1). This suggests that multiple SP_L acquisitions can have

394   the same performance of multiple BP acquisitions, meaning that a 2D single-plane US

395   with multiple slices can potentially achieve the same accuracy of 2D bi-plane US.

396   However, the errors' variability was superior when using SP_L, which indicates that it is

397   less repeatable than BP. Other researchers have tested the use of multiple slices in

398   different approaches. Ahmad *et al.* reported a registration error of 0.8 mm [20]. However,

399   tests were made in a kidney tumor phantom with 3 cm of width and 5 cm of length. In

400   opposition, our tests were performed in a large model - porcine kidney phantoms with

401   5-7 cm and 10-13 cm of width and length, respectively, with a registration error of 1.80

402   mm (AVD for 9 slices SP_L, see Table 1). Likewise, Yu *et al.* concluded that multi-view

403   3D reconstructions from sparse 2D US images leaded to more accurate volume

404   quantification compared to single views in cardiac images [39]. Similarly, Bogush *et al.*

405   concluded, for simple objects, that 8 to 10 cross-sections were sufficient to obtain a

406   mean volume error lower than 5% [40], which is consistent with our results (mean volume

407   error ~9% for DSC). Nine slices presented on average the lowest registration errors,

408   and the biplane, with pairs of slices (i.e. 18 slices), does not seem to considerably

409   improve the registration accuracy.

410 As abovementioned, previous works have tried to register 2D US with CT or MRI for

411 image-guided PRA based on surface-based registration. Mozer *et al.* considered rigid

412 transformations between pre and intraoperative data, where CT and sparse 2D US

413 (coupled to an optical tracker) images were used. They reported a repeatability and

414 closed-loop accuracy of 0.79 mm and 1.2 mm, respectively [13]. However, no gold

415 standard was available, and the authors tested the registration strategy using a single

416 patient. Li *et al.* presented an orthogonal-ICP strategy using two pairs of orthogonal US

417 images (aligned and parallel to transverse and longitudinal planes of the kidney), which

418 were selected from sparse images at the maximum exhalation position. The results

419 revealed a root-mean-square (RMS) target registration error of 3.53 mm in four healthy

420 volunteers when fused with MRI data [12]. This result is close to our results when a

421 similar number of slices were used during the registration process. Indeed, SP_L using

422 five slices and BP using two slices (i.e. two pairs of orthogonal slices) presented an

423 average P2P distance of 3.42 mm and 3.45 mm (for ICP2, see Table 1), respectively.

424 Despite the interesting results, Li *et al.* required the use of an optical tracking based

425 respiratory gating technique to obtain the maximum exhalation position. All steps were

426 performed at this specific position, including image capture, registration, segmentation,

427 and puncture. We believe that a safer interventional strategy should rely on the

428 continuous monitoring of the kidney position based on US images. Li *et al.* also tested

429 the same approach in a pig model, although using a statistical shape model (SSM) to

430 three-dimensionally reconstruct the kidney, with a RMS error around 1 mm [14]. Thus, 3D

431 kidney reconstruction from 2D US images has the potential to be used in image-guided

432 PRA, and new strategies should be studied to improve these methodologies. The

433 concept of 2D US with surface reconstruction has also been used for bone [41] and

434 artery [42] interventions.

435 Regarding Hypothesis 3: *"Can different US probe's movements (acquiring kidney slices*

436 *at different positions) benefit the final alignment between US and CT kidney surfaces?",*

437 the results proved that different probe movements can give a better performance

438 during the registration process. The results suggested that yaw_{US} movements (i.e. a

439 sweep movement along the longitudinal view, see 3-I) leads to a better performance,

440 specifically for SP_L acquisitions (with an error of ~2 mm). This suggests that a single-

441 oriented sweep may obtain a valid alignment when 2D single-plane US acquisitions are

442 used. This can be relevant because 2D probes are more common in the urology field

443 than 4D ones. Although yaw_{US} movements using BP presented slightly higher errors

444 when compared with single-plane yaw_{US} motion, they had a lower IQR. It is relevant to

445 mention that yaw_{US} movements sliced the kidney equally for BP and SP_L. However, BP

446 differed on the presence of the central transverse plane. Therefore, this transverse

447 plane seems to positively affect the registration process by reducing the method's

448 sensitivity to the contours and initial alignment. In addition, the results presented in

449 Figure 5 revealed that when $roll_{CT}$, $pitch_{CT}$, and yaw_{CT} ranged between -50º and 50º,

450 the average errors were below 3 mm for the ICP2 method. As such, an initial and rough

451 pre-alignment of the preoperative data with the intraoperative one seems to be

452 mandatory for the ICP method. Among the two studied ICP methods, different

453 performances and error magnitudes were obtained throughout this study, as expected.

454 Previous studies revealed that the *point-to-plane* metric (i.e. ICP2) converges quicker

455 and, typically, with lower errors [32]. Figure 6 suggests that slicing the kidney along the

456 central longitudinal view may improve the registration. This may be related with the full

457 slicing of the longitudinal view that preserves more shape information of the kidney.

458 Overall, the results suggest that surface-based registration for image-guided PRA is a

459 valid strategy for intraoperative image registration, even from a single-oriented

460 acquisition. In addition to be a multi-modal approach, which can extend these results to

461 MRI for example, this approach has the potential to be applied to different

462 interventions. Indeed, the segmentation algorithm can be adapted for different

463 anatomical structures under intervention. In our study, although we studied only the

464 fusion based on the kidney surface, segmentation of internal structures [43] (such as

465 renal calyx, renal medulla, renal cortex, renal column, etc.) and adjacent organs [44]

466 (such as liver, intestines, vessels, etc.) may help improve the intraoperative fusion.

467 However, future work must be performed to assess this hypothesis.

468 During the registration process, it was assumed rigid movements between tests, while

469 scale, shear or nonrigid changes were disregarded. However, these can occur in real

470 scenarios and can affect the alignment results, namely due to respiratory and small

471 non-rigid movements of the tissues. This fact is one of the limitations of this study. Only

472 a 4D US acquisition would provide the necessary information to manage the full set of

473 possible transformations during image-guided PRA. As far as we know, currently, this

474 information is not freely shared by manufacturers. Notwithstanding, as an advantage,

475 2D US data has usually better quality and higher amount of details than 3D/4D volume

476 data, being a widely used tool in urological interventions. So, these reasons support

477 why we still focus on 2D US imaging for multi-modal fusion. Therefore, the current

478 findings are directly applicable in clinical practice, as long as real-time segmentation

479 and registration algorithms are developed.

480 In summary, the results showed that SP_L and BP acquisitions had the best performance

481 when multiple slices were used. The yaw_{US} movements, i.e. a large sweep along the

482 central longitudinal view, presented the best results with an average error of ~2 mm.

483 In future, current strategy should be tested in an image-guided framework integrating

484 automatic segmentation of both image modalities, an inter-modality registration

485 strategy, tracking and puncture guidance in real-time.

486

487 5 CONCLUSIONS

488 This work assessed the optimal 2D US acquisition protocol to improve surface-based

489 registration between CT and US data for image-guided PRA. It was observed that the

490 use of contours from multiple planes and specific sweep movements of the US probes

491 may be crucial to improve the final registration between CT and US data. Surface-

492 based registration for image-guided PRA suggests being a valid strategy for

493 intraoperative image fusion. This strategy has the potential to be applied to different

494 image modalities and interventions, and the presented methodology has the potential

495 to be used to assess their feasibility.
