Abstract

Metronidazole (MNZ) is a recalcitrant antibiotic with toxic and carcinogenic effects in aquatic environments. In this work, $Fe_5(PO_4)_4(OH)_3 \bullet 2H_2O$ (giniite) particles were synthesised with three different alkaline cations (Li^+, Na^+ and K^+) and used as Fenton catalysts for MNZ removal. It is shown that the addition of different cations during the hydrothermal synthesis process promote different morphologies from asterisk-like to flower-like and branches-like, maintaining the crystalline structure of pure giniite. The photocatalytic activity of these particles was then evaluated through the degradation of MNZ under sunlight radiation for 9 hours. The results indicate that the alkaline cation has a predominant role in the photocatalytic efficiency, as demonstrated by the superior degradation efficiencies of Na@giniite particles (91.2% and 72.5% with giniite concentration of 0.2 g/L and 0.07 g/L, respectively), related with its high surface area (10.7 m^2/g). Thus, it is demonstrated the suitability of Na@giniite particles as Fenton catalyst for MNZ removal from water.

Keywords: advanced oxidation process, emergent pollutants, giniite, metronidazole, sunlight irradiation

1. Introduction

Water pollution has become a severe environmental problem all over the world, and the treatment of organically contaminated wastewater is a growing concern [1]. Among all, antibiotics have been frequently found in both aquatic and terrestrial environments. The excessive consumption of these compounds leads to their presence in water, inducing proliferation of bacterial drug resistance and increasing the concern about their toxicity and poor metabolisation [2]. Metronidazole (MNZ) is a widely used antibiotic in the treatment of several infections caused by anaerobic bacteria, bacteroides and protozoa [3], it is also used as an additive in fish and poultry feed to eliminate parasites [4]. As a consequence, MNZ is accumulated in animals and effluents from hospitals and industries [5, 6]. It is considered toxic to aquatic environments, genotoxic to humans, carcinogenic and mutagenic [7]. Due to its low degradability and high solubility in water, the efficient removal of MNZ from wastewater is an urgent need.

Advanced oxidation processes (AOPs) are photochemical technologies used for the degradation of resistant organic compounds like pharmaceuticals [8], pesticides [9] or phenolic compounds [10]. AOPs are based on oxidation reactions and consequent formation of hydroxyl radicals, which can break links in resistant and stable organic compounds. In the Fenton process, hydroxyl radicals are formed through the reaction of H_2O_2 with Fe^{2+} ions under strongly acidic conditions. It consists of the oxidation of Fe^{2+} to Fe^{3+} along with the reduction of H_2O_2, to produce $^{\bullet}OH$ radicals. Compared with other A.O.P.s, Fenton process is widely applied due to its simple operation, broad application range, fast degradation and mineralisation of compounds and strong anti-interference ability [11]. However, the application of Fenton process is limited by a sharp working pH range (2.5 – 3.5), the requirements for further separation and the significant amount of ferric hydroxide formed during the process [12]. To overcome these limitations, some Fenton catalysts, such as iron oxides [13], carbon-based composites [14] and iron phosphates [12], have been successfully prepared.

Iron phosphates are materials with exciting properties, such as the oxidative dehydrogenation catalysis and the crystal chemistry [15]. In particular, giniite, Fe_5 $(PO_4)_4(OH)_3 \bullet 2H_2O$, is used for photocatalytic degradation of organic dyes [16-18] and in lithium-ion battery applications [19]. Recently, *Duan et al.* [16] prepared giniite microcrystals and evaluated their photocatalytic activity, showing that their performance is highly dependent on the exposed faces. Different methods are used for the synthesis of synthetic giniite, such as sol-gel, solid-state reaction, electrochemical synthesis, or hydrothermal, among others [20-22].

Giniite obtained by hydrothermal synthesis process, using different inorganic and organic precursors and various parameters, as temperature, pH, stoichiometric ratios and time of synthesis, was prepared to obtain a wide variety of morphologies [19, 23].

In this work, the influence of alkaline cations (Li^+, Na^+, K^+) during the synthesis of giniite on crystal morphology was investigated. Three different morphologies were obtained, and their photocatalytic activity was evaluated through the degradation of MNZ under sunlight radiation.

2. MATERIALS AND METHODS

2.1. Reagents

Metronidazole (M= 171.16 g/mol), with the chemical formula $C_6H_9N_3O_3$ and a maximum absorption at a wavelength of 284 nm, was purchased from Merck. Hydrogen peroxide (H_2O_2, 30% w/w), sodium hydroxide (NaOH, 97%) and sulfuric acid (H_2SO_4, 95%) were purchased from HACH Company. All solutions were prepared with ultrapure water (Milli-Q). Phosphoric acid (85%, H_3PO_4), lithium hydroxide (97%, LIOH) and potassium hydroxide (97%, KOH) were purchased from Merck. Iron nitrate (99%, $FeNO_3$) was purchased from Panreac.

2.2. Synthesis of giniite

The synthesis of giniite was performed according to previous studies [19]. The first step was the preparation of three separated solutions: (1) dissolution of 0.29 g of H_3PO_4 in 5 g of UP water; (2) dissolution of 0.85 g of $FeNO_3$ in 10 g of UP water; (3) dissolution of 0.44 g of LiOH, NaOH or KOH in UP water, with pH adjustment to 4. The second step was the mixing of the three solutions, following the order 1+2+3. The mixture was then magnetically stirred for 5 minutes to achieve homogeneity and, after that, placed into a Teflon-lined stainless-steel autoclave to heat at 230 ºC for 72 hours. Finally, the powders were filtered, washed with water and dried overnight at 60 ºC.

2.3. Characterisation of giniite

The crystal morphological characterisation was assessed by scanning electron microscopy (SEM) with an FEI. Nova 200 (FEG/SEM). The crystal structure and phase composition of the three giniite samples were evaluated through X-ray diffraction (XRD), using a Bruker D8 Discover diffractometer. The XRD parameters were: θ-2θ scan mode; a range of 0-60º with a scan step of 0.06º/s. The chemical structure of the prepared giniite was evaluated by Fourier Transformed Infrared Spectroscopy (FTIR), with a Jasco FT/IR-4100 system, carried out from

4000 to 600 cm^{-1} with a resolution of 4 cm^{-1} and 64 scans in the attenuated total reflectance (ATR) mode.

Samples porosity and surface area were determined by mercury intrusion porosimetry (MIP) in a Quantachrome Instruments Poremaster-60 GT operating in the pressure range from vacuum (10^{-4} MPa) to 414 MPa. Samples were degassed in situ at 110 °C during 12 h before measurement. A contact angle of 140° and a surface tension of 480 dyn/cm for mercury and a pressure equilibration time of 11 s were used. Before the measurement of MIP the He density for all the samples were measured in a Quantachrome Instruments automatic Micro Ultrapycnometer.

2.4. Photocatalytic assays

The Fenton photocatalytic activity of giniite was evaluated through the direct contact between giniite particles and a 10 mg/L MNZ solution. The used experimental setup is shown in **¡Error! No se encuentra el origen de la referencia.**Figure 1.

**Figure 1. (a)** ~~The s~~Schematic representation of the experimental setup used for the photo Fenton photocatalytic assays; **(b)** picture of the real setup.

Photocatalytic experiments were performed in a beaker with 150 mL of MNZ solution and two different concentrations of giniite particles (0.2 and 0.07 g/L). 2 mL of H_2O_2 were added to the solution simultaneously with pH adjustment (pH = 2.8) using H_2SO_4 or NaOH. The experiments were then carried out under magnetic stirring for 9 hours and under sunlight radiation. The solar flux was measured every hour using a pyranometer (KIPP & ZONEN, CMP11) coupled to a data acquisition software. The aliquots were withdrawn at regular times, subjected to vigorous centrifugation (6000 rpm, 20 min) to remove the ginniite particles, and filtered through 0.45 mm Millipore filters.

2.5. Analytical methods

The absorbance of MNZ was measured at defined intervals of time by UV-visible spectrophotometry (Shimadzu UV1800), in the range of 200-400 nm, and the photocatalytic degradation was analysed by the evaluating of the absorbance variation of the principal peak at 320 nm, using 1 cm quartz cell. The photocatalytic efficiency (%) was calculated using equation 1:

$$R \ (\%) = \frac{(C_0 - C)}{C_0} \times 100 \qquad (Eq.\,1)$$

where C_0 and C are the initial and equilibrium MNZ concentrations (mg/L), respectively.

MNZ mineralisation was evaluated by High-Performance Liquid Chromatography (HPLC, Waters, U.S.A.) equipped with a UV detector. The analytical column was a Diamonsil (R) C18 (250×4.6 mm, 5 µm), and the mobile phase was composed by acetonitrile/water, (30/70, v/v). The flow rate was set at 1.0 mL/min, and the injection volume was 20 µL. The detection wavelength was 348 nm.

3. RESULTS AND DISCUSSION

3.1. Giniite main characteristics

The morphology of the obtained samples, synthesised by the different precursors (LiOH, NaOH and K.O.H.) and the same pH=4, is presented in the SEM images of Figure 2~~Figure 2~~. The obtained iron phosphates present different morphologies for each alkaline cations (Li$^+$, Na$^+$ and K$^+$) of the hydroxides precursors. Morphologies include asterisk-like (Figure 2~~Figure 2~~ (a)), flower-like (Figure 2~~Figure 2~~ (b)) and branches-like (Figure 2~~Figure 2~~ (c)), related to the use of LiOH (Li@giniite), NaOH (Na@giniite) and KOH (K@giniite) precursors, respectively. The Li@giniite sample is formed by four or five orthogonally arranged segments that hold a particle diameter between 5-10 µm. The Na@giniite sample possesses pyramid-like intergrowths with uniform particle size between 5-6 µm. The K@giniite sample form dendrites orthogonally arranged with sizes between 20-40 µm.
Figure 2. SEM images of the synthesised samples obtained with the (a) LiOH, (b) NaOH and (c) KOH precursors.

The observed morphology variations among the different particles demonstrate that the cation precursors used in the hydrothermal synthesis, directly influence the morphology during the crystal grow. The interaction between each cation leads to cap the particle surface during the growth of the atomic planes. Comparing the lithium (Li^+) and sodium (Na^+) with the potassium (K^+) cation, the last one favours a planar structure with high dimensions due to its higher atomic radius. In contrast, the smaller atomic radius cations (Li^+ and Na^+) tend to yield smaller particles with orthogonal shape [19].

The surface areas of each structure were estimated by mercury intrusion porosimetry. The Na@giniite shows the highest surface area, 10.7 m^2/g, and the K@giniite the lowest one, 2.9 m^2/g. A more significant difference is observed between the Na@giniite spherical morphology and the branches-like morphology of K@giniite.

The crystalline structure of each sample was studied by XRD using Le Bail fits, and the results are presented in Figure 3Figure 3 (a), (b), and (c), showing that the samples crystallise as giniite structure, regardless of the cation used as a precursor, proven by the identification of characteristics peaks of giniite (JCPDS card no.: 45-1436). Moreover, all samples show well-defined peaks establishing the crystalline structure, and no other phases were found. The obtained diffractograms allowed to build a crystal structure, represented in Figure 3 (d). The presence of the studied alkaline cation during the synthesis does not influence the formation of

the giniite crystalline structure. Since in this study, parameters as temperature, time and pH were well controlled and kept constant, it is possible to affirm that the addition of the different cations does not influence the giniite structure, but allows to control its morphology, as previously mentioned (Figure 2Figure 2) [24].
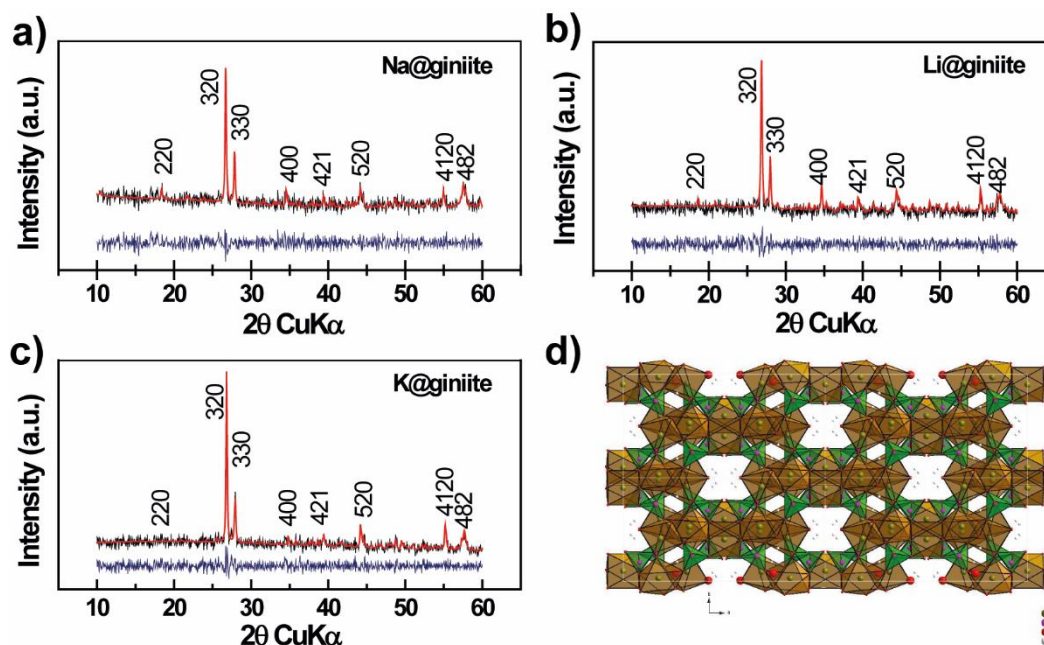

Figure 3. (a), (b), (c), Le Bail fits of the samples prepared by hydrothermal synthesis of giniite with different alkaline cations (giniite - JCPDS card no.: 45-1436), **(d)** giniite structure obtained using Crystal Maker® software and representing Fe (yellow), P (pink), O (red), and H (white).

FTIR also identified the giniite structure and the results (available in supplementary information, Figure S1) allows to identify the pure phase by the characteristics well- and broad-defined vibrational bands of giniite at 751, 775, 943, 998, 1021, and 1074 cm^{-1}. The vibrational bands between 800 and 1074 cm^{-1} are assigned to the PO^4 bonds (asymmetric stretching between the P and O atoms). For lower wavenumber, the bands at 751 and 775 cm^{-1} are assigned to the Fe and O bonds [24]. The absence of symmetric stretching phosphate groups at 923 cm^{-1} also indicate the presence of the giniite phase without impurities.

3.2. Fenton photocatalytic degradation of MNZ

The Fenton photocatalytic activity of giniite particles was evaluated by exposure of MNZ (10 mg/L) to sunlight radiation, arround 853.15 W/m^2 , for 9 hours. The results are presented in Figure 4Figure 4.
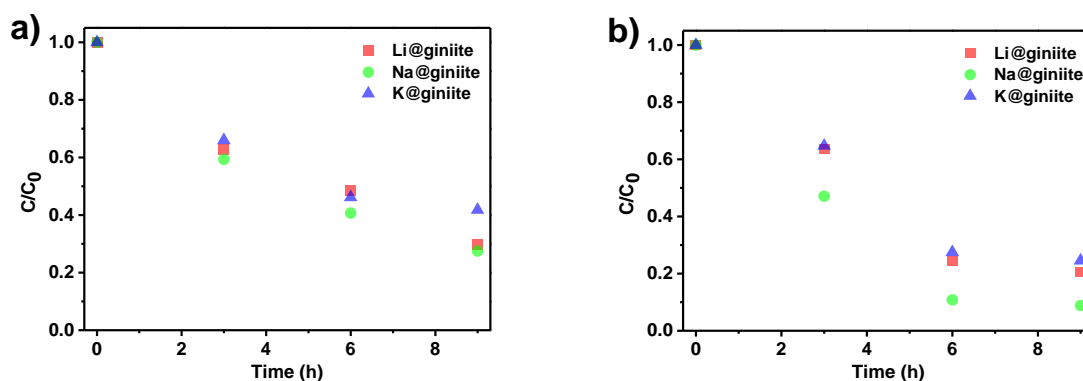

Figure 4. Photo-Fenton photocatalytic degradation of MNZ (10 mg/L) at pH=2.8 with **(a)** 0.07 g/L and **(b)** 0.2 g/L of giniite particles, under sunlight radiation exposure of 9 hours.

As a control test, the adsorption of MNZ to the surface of giniite particles was assessed in the dark. Additionally, a second control was performed by exposing MNZ to sunlight radiation without giniite particles. The MNZ removal was approximately 1%, for both tests, after 9 h of the experiment (available in the supplementary information, Figure S2).

The degradation rates of MNZ were determined by fitting the pseudo-first-order model. Thereby, enough amount of H_2O_2 was produced in the Fenton process, and OH concentration was considered as constant. The apparent rate constants were determined by equation 2:

$$\ln\left(\frac{C_0}{C}\right) = k_{app}t \qquad (Eq.\,2)$$

where C_0 and C are the initial and MNZ concentration at time t, respectively, and k_{app} is the first-order rate constant.

Two different concentrations of giinite particles, 0.07 and 0.2 g/L, were tested to evaluate its effect on the degradation efficiency. Figure 4Figure 4 (a), indicates that Na@giniite (72.5% and 0.1418 h^{-1}) and Li@giniite (70.3% and 0.1301 h^{-1}) particles present the higher degradation efficiencies, while K@giniite present lower degradation efficiency and rate (58.2% and 0.0992 h^{-1}). Such differences are explained because of the significant morphology variations among the tested particles, as previously discussed and supported by Figure 2.

Figure 4Figure 4 (b) shows the degradation of MNZ with 0.2 g/L of giniite. After 9 h of exposure to sun radiation, all the giniite samples show a degradation efficiency higher than 75%. The highest degradation efficiency was observed with Na@giniite particles (91.2%), while samples of Li@giniite and K@giniite presented similar degradation efficiencies (79.4%

and 75.5%, respectively). The reaction rates indicated that Na@giniite particles promoted a faster degradation of MNZ, with a reaction rate of 0.2918 h^{-1}. Li@giniite and K@giniite presented similar reaction rates (0.1899 and 0.1692 h^{-1}, respectively).

By analysis of both Figure 4Figure 4 (a) and (b) it is observed that higher concentrations of giniite result in enhanced efficiencies and degradation rates for all the tested giniites. The selected concentrations are within a range mentioned in literature, and the 0.2 g/L concentrations seems to be enogh to attaim a complete MNZ degradations. However, only the Na@giniite represents a significant improvement of efficincy. The superior degradation efficiency and rate of Na@giniite particles can be related to its crystal morphology (Figure 2Figure 2). Different alkaline cations lead to variations on the average size of particles and morphologies, which leads to changes in the surface area, causing the observed differences in degradation efficiencies. According to the surface area results, obtained through M.I.P., Na@giniite and K@giniite show a surface area of 10.7 and 2.9 m^2/g, respectively. In this way, Na@giniite offers a higher surface area and further active sites that allow MNZ adsorption to its surface, resulting in a superior degradation efficiency of 91.2%.

Very few works were found related to giniite application to Fenton photocatalytic processes and listed in Table 1. Although this information allows putting in perspective our results, it is essential to highlight that direct comparison with our data are impossible, as the experimental conditions and methodology used in each work are different.

Table 1 – Comparative study on giniite application to Fenton photocatalytic degradation of contaminants.

Pollutant	Pollutant concentration	Giniite	Size (μm)	Radiation	Degradation (%)	Time (h)	Ref.
Rh B	10 mg/L	20 mg (100 ml)	10-50	-	≈ 99%	1	[25]
MB	1×10^{-5} M	50 mg (100 ml)	20	500 W (λ> 290 nm)	≈ 100	6	[23]
Rh B	1×10^{-5} M	50 mg (100 ml)	3.5 - 4.5	300 W (λ >420 nm)	≈ 100	2.5	[26]
MB	10 mg/L	30 mg (100 ml)	1.2 - 1.4	150 W (λ > 420 nm)	99.5	2	[12]

From the works listed in Table 1, it is possible to perceive that giniite proved is efficiency by completely degrading RhB and MB under different radiation intensities (from 150 W to 500 W) and exposure times, despite the different sizes used in the works (ranging from 20 to 1.2 μm). However, these works use artificial radiation, making the process expensive; additionally,

the presented works are focused on dyes degradation, which absorb visible range radiation and favours photodegradation. Our work tested higher volumes (150 ml), used inexpensive sunlight radiation and focused on a recalcitrant micropollutant degradation, MNZ.

3.3. Mineralisation and degradation mechanism of MNZ

UV-VIS and HPLC-UV analysis allowd to evaluate degradation the mineralisation of MNZ after the tretments with the different giniites, as presented in **Figure 5**Figure 5.

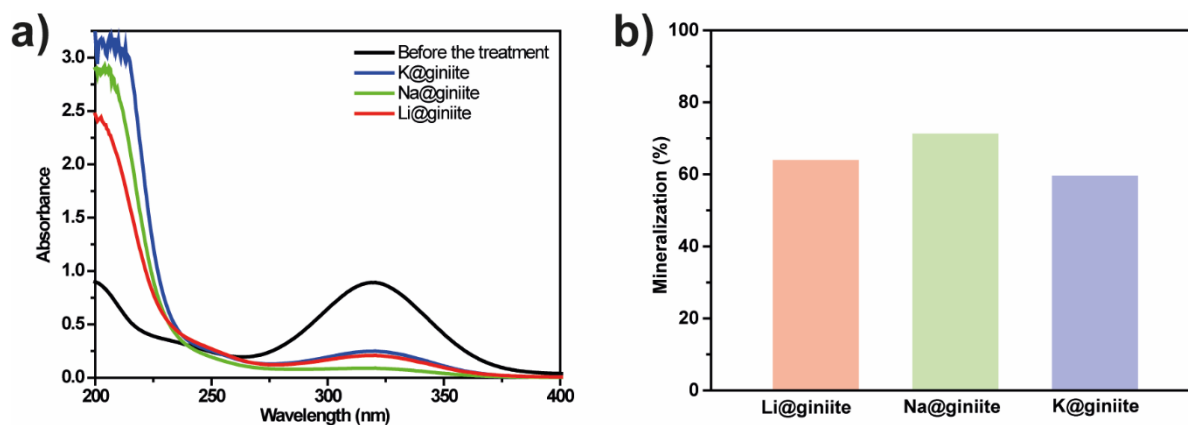

Figure 5. **(a)** UV-VIS spectra of MNZ. before and after the treatment with Li, Na, and K@giniite; **(b)** Mineralisation of MNZ. by Li, Na, and K@giniite particles measured trough HPLC-UV.

The evaluation of mineralisation is a significant parameter, as unstable intermediates more toxic than MNZ can be produced in the photocatalytic process and remain in the solution due to incomplete mineralisation [27]. In fact, Figure 5Figure 5 shows that all the tested giniite particels are unable to completely mineralise MNZ. These particles achieve MNZ mineralisations around 60-72%, and a mineralisation maximum of 71.5% is obtained for Na@giniite. Despite the significantly high mineralisation achieved, by-products may be present in water after the photocatalytic process. In this way, it is important to understand the MNZ degradation mechanism. A possible mechanism of MNZ degradation is illustrated in Figure 6Figure 6.
Figure 6. General degradation mechanism of MNZ (adapted from [28]).

One route for MNZ degradation is started by hydroxylation and denitration, leading to the formation of (1). This subproduct is then oxidised, and the subproduct (4) is formed. The second route initiates with the hydroxyethyl-cleavage of MNZ, producing (2). Similar reactions yield the formation of subproduct (5). The third route of MNZ is the ˙OH attack over the hydroxyethyl group, leading to the creation of (3), which is then oxidised to produce (4). Further oxidations of heterocyclic intermediates – subproducts (3), (4) and (5) – lead to the formation of carboxylic acids and the complete mineralisation into CO_2 and H_2O [28, 29]. According to the literature, the mineralisation of MNZ reduces its ecotoxic effects in aqueous solutions[30].

4. CONCLUSIONS

This work shows the influence of three different alkaline hydroxides (NaOH, LiOH, and KOH) during the hydrothermal synthesis, in the crystal morphology of giniite and its Fenton photocatalytic activity against MNZ. The different types of alkaline cations promote different morphologies including asterisk-like, flower-like and branches-like for LiOH, NaOH and KOH, respectively, also resulting in different surface areas between 10.7 and 2.9 m^2/g for Na@giniite and K@giniite, respectively. On the other hand, the pure crystalline structure and chemical structure of the giniite remain the same for the samples prepared with the different alkaline cations. Concerning the influence of catalyst concentration and alkaline cation in its efficiency, it is shown that giniite concentration plays an essential role in Fenton photocatalytic activity, increasing giniite concentration leading to more efficient degradation of MNZ. The alkaline cation has a significant impact on the photocatalytic activity, Na@giniite presenting the highest degradation efficiency when compared with Li and K@giniite (12 and 16% higher efficiency

for 0.2 g/L; 2 and 14% higher efficiency for 0.07 g/L, respectively) mainly due to its higher surface area. Thus, the results indicate the suitability of Na@giniite particles for metronidazole and related compounds removal from water under sunlight radiation.
