Estimating Friction Factors in a Fouled Annulus

L. F. MELO and J. D. PINHEIRO

Centro de Química Pura e Aplicada, University of Minho, Braga, Portugal

Fouling of heat transfer surfaces modifies the associated conductive thermal resistance and convective heat transfer coefficient. Often, the latter varies as a result of changes in the roughness of the deposition surface. If fouling is being studied in an annular heat exchanger, deposits may form on both surfaces of the annular cross section, and an estimation of the friction factors of each fouled surface is needed. In order to evaluate these factors a simple method can be used as described in this paper, based on pressure drop measurements and current equations. Experimental results are reported and appear to support the method.

L’encrassement des surfaces de transfert de chaleur modifie leur resistance thermique conductive et leur coefficient de transfert de chaleur par convection. Celui-ci change, souvent, comme resultat de variations de la rugosite de la surface causees par des depots. Dans un echangeur de section annulaire, les depots peuvent se former sur les deux surfaces de l’espace annulaire. Il est donc necessaire de calculer les coefficients de frottement de chacune de ces surfaces, ce qui peut etre accompli en appliquant la methode decrite ici, basee sur des equations simples et des mesures de la perte de charge. Les resultats experimentaux semblent confirmer la validite de cette methode.

Small-scale annular heat exchangers are commonly used in experimental fouling studies. During the fouling tests the build-up of deposits causes changes in the pressure drop and, particularly, in the friction factors of both the inner and the outer tubes. Usually, the inner wall of the annular section is the fouled surface of greater interest, and the calculation of its friction factor is important in evaluating the actual convective heat transfer coefficient and the thermal resistance of the deposited materials (Bott and Walker, 1971; Epstein, 1978).

A simple method for estimating the friction factors associated with the inner and outer surfaces of the annulus is described below, based on pressure drop measurements and current equations. It is assumed that the deposit thickness is much smaller than the annulus width, so that blockage effects may be neglected. This is a reasonable assumption in most fouling rigs, as Epstein (1978) pointed out; it was again confirmed by the results of the fouling test reported below.

The total force exerted by the fluid on the solid walls is (Bird et al., 1960):

\[ F_1 + F_2 = \pi \Delta P (r_2^2 - r_1^2) \]  \hspace{1cm} (1)

The shear stresses and the friction factors on each wall are given by:

\[ \tau_i = F_i/2\pi r_i L \]  \hspace{1cm} (2)

\[ f_i = 2\pi r_i/\rho u^2 \]  \hspace{1cm} (3)

\( i = 1 \) or \( 2 \), depending on the surface being considered.

Thus, from Equations (1) to (3) one gets:

\[ f_1 r_1 + f_2 r_2 = \Delta P (r_2^2 - r_1^2)/L \rho u^2 \]  \hspace{1cm} (4)

At the beginning of the fouling test the inner and outer surfaces are clean and smooth, and the ratio of the corresponding friction factors is (Walker and Rothfus, 1959):

\[ (f_1)_b/(f_2)_b = (\tau_1)_b/(\tau_2)_b = r_2 (r_m - r_1)/(r_0^2 - r_1^2) \]  \hspace{1cm} (5)

In laminar flow, the radius of maximum fluid velocity, \( r_m \), can be predicted theoretically (Bird et al., 1960):

\[ r_m^2 = (r_2^2 - r_1^2)/2 \ln (r_2/r_1) \]  \hspace{1cm} (6)

According to the experimental work of Rothfus, Walker and Whan (1958) and of Walker and Rothfus (1959), Equation (6) appears to hold also for turbulent flow; their results show that the deviation is only 2.5% at \( Re = 3000 \) and decreases with increasing \( Re \). Hence, it is assumed that \( r_m \) has similar values for laminar and turbulent regimes. This assumption is further confirmed by Brighton and Jones (1964) for \( r_1/r_2 > 0.5 \).

In Equations (4) and (5) the unknowns are: \( f_1, f_2 \) and \( \Delta P \). Therefore, if the initial value of \( \Delta P \) is measured and entered into Equation (4), the initial values of the friction factors of both surfaces are determined.

When the annulus is fouled, Equation (6) cannot be safely used because of the unpredictable effects of the rough deposit on the velocity profile, particularly on \( r_m \). However, values of \( f_1 \) and \( f_2 \) for the fouled annulus can be calculated if the fouled inner tube is replaced by a clean, but otherwise similar, tube, and the pressure drop measured without cleaning the outer tube. With this procedure, two different \( \Delta P \) values, related to the fouled annulus condition — namely, \( (\Delta P)_1 \) and \( (\Delta P)_2 \) — are available and can be used in Equations (7) and (8), these being obtained from Equation (4) for the following two cases:

Inner tube clean, outer tube fouled:

\[ (f_1)_b r_1 + (f_2)_b r_2 = (\Delta P)_1 (r_2^2 - r_1^2)/L \rho u^2 \]  \hspace{1cm} (7)

Both tubes fouled:

\[ (f_1)_b r_1 + (f_2)_b r_2 = (\Delta P)_2 (r_2^2 - r_1^2)/L \rho u^2 \]  \hspace{1cm} (8)

Solving for \( (f_1)_b \) and \( (f_2)_b \), these friction factors of each fouled surface are obtained.

Alternatively — instead of replacing the fouled inner tube by a clean tube — one can replace the outer tube and use the following equation instead of Equation (7):

\[ (f_1)_b r_1 + (f_2)_b r_2 = (\Delta P)_2 (r_2^2 - r_1^2)/L \rho u^2 \]  \hspace{1cm} (9)
Solving now Equations (8) and (9) for \(f_i, k\) and \(f_2, k\), one should obtain the same values as before.

The method described was used by Melo and Pinheiro (1984) to estimate friction factors in a fouled annular heat exchanger with a radius ratio \(r_1/r_2 = 0.7\) and an equivalent diameter of 11 mm, in which kaolin deposited from a kaolin-water suspension flowing at a Reynolds number of 7000. The results obtained are shown in Table 1 from which it is possible to note that the relative increase in the friction factor of the inner tube is greater than the increase in the overall friction factor. The latter is directly calculated from the pressure drop measurements, through:

\[
f = \frac{\Delta P_d}{2L \rho u^2} \quad \ldots (10)\]

where \(D_r = 2(r_2 - r_1)\). A simple dependence of \(f\) on \(f_1, f_2, r_1\) and \(r_2\) can be obtained from Equations (4) and (10):

\[
f = \frac{(f_1 \cdot r_1 + f_2 \cdot r_2)}{(r_1 + r_2)} \quad \ldots (11)\]

which is valid for any annulus (clean or fouled).

The difference between the two values of \((f_1, k)\) presented in Table 1 will be mainly due to a slight difference (2.1%) in the roughness of the two inner tubes used in the experiment (which can be assessed before the fouling test). Note that the overall friction factor for the fouled annulus calculated with Equation (11) using \((f_1, k) = 10.0\) is 9.0, deviating about 1% from the measured \(f\).

The fact that the thickness of the kaolin deposit (70 microns on the average) is much smaller than the annulus diameter minimizes the possible blockage effects. In the present case the increase in fluid velocity due to blockage is only 2%, leading to a minor raise in the convective heat transfer coefficient (1.6%, obtained from the usual heat transfer correlations), while the change in that coefficient due to roughness is about 18%, as given by the Norris’ correlation (Walker and Bott, 1973).

In cases where blockage effects are of some practical importance, although not prevailing, the method can still be used if an estimate of the deposit’s thickness is available, enabling the correction of the fluid velocity in Equations (7) and (8). It should also be stressed that the effects of fluid velocity and of roughness in the convective heat transfer coefficient are qualitatively the same, because they both tend to increase turbulence.
